Various ponders have appeared that the antigenic determinant of ABO blood gather framework is closely related in biochemical terms to the antigenic determinants of the Hh, P, Lewis and Ii blood bunch framework. The blood group antigens of each of this system are formed by the addition of specific sugar to the oligosaccharide precursor chain which may be bound through sphingosine to fatty acids (glycolipid) or through serine or threonine to a peptide chain (glycoprotein). The direct gene product of each of these blood group systems are the glycosyltransferase enzyme which catalyse the addition of specific sugar thus conferring the specified blood group activity to the glycolipid or glycoprotein molecule.When considering such patients for transfusion, as it were blood of indistinguishable Bombay sort can be securely transfused.During cell grouping or forward grouping, Bombay blood group would be categorized as O group because it would not show any reaction to anti-A and anti-B antibodies just like a normal O group would do.When a cross matching with distinctive blood sacks of O gather is done, at that point it would appear cross-reactivity or contradiction[8]. Hence a thorough evaluation should be done for identification. Therefore, for detection of Bombay blood group, reverse grouping or serum grouping has to be performed. Thus, this method which is serum grouping or reverse grouping has to be performed in every transfusion medicine department, blood bank or blood donor centres so as to reduce the risk of fatal hemolytic transfusion reactions.Bombay type is very peculiar because in routine tests for blood grouping it is an O type, but during cross matching procedure donor's O-type cells get clumped with the serum of Bombay type recipient, as Bombay type possesses suppressed H-gene. When considering such patients for transfusion, only blood of identical Bombay type can be safely transfused. Therefore, it becomes a real challenge for the anesthesiologist to manage such type patients without having units of red packed cell. And this article reveals the true importance of blood group matching and serum matching prior to blood transfusion. Even though the probability of occurrence of Bombay blood group is very less, we should never assume things. This will always provide a safe and quality practice.

Brachial Plexus Injury

Anitha.D.R [1], Saravana Kumar [2], Sri Sakthi.D [3]
Graduate Student [1],Lecturer [2],Department Of Anatomy,
Reader [3],Department Of Public Health Dentistry,
Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstract

To Review The Function, Anatomy, Causes, Classification, Diagnosis And Treatment Of Brachial Plexus Injury. The Brachial Plexus Is A Network Of Nerve Running From The Spine .It Is Formed By The Ventral Rami Of The Lower Four Cervical And First Thoracic Nerve Roots (C5-C8, T1). It Proceeds Through The Neck, The Axilla (Armpit Region), And Into The Arm. It Is A Network Of Nerves Passing Through The Cervico-Axillary Canal To Reach Axilla And Innervates Brachium (Upper Arm), Ante Brachium (Fore Arm) And Hand.The Brachial Plexus Is Responsible For Cutaneous And Muscular Innervation Of The Entire Upper Limb, With Two Exceptions: The Trapezius Muscle Innervated By The Spinal Accessory Nerve And An Area Of Skin Near The Axilla Innervated By The Intercostobrachial Nerve .Lesions Can Lead To Severe Functional Impairment. Brachial Plexus Injuries Affects The Nerves Which Send Signals From The Spine To Your Shoulder.Brachial Plexus Injury Is An Umbrella Term For A Variety Of Conditions That May Impair Function Of The Brachial Plexus Nerve Network. The Majority Of Paediatric And Adult Brachial Plexus Injuries Are Caused By Trauma. A Brachial Plexus Injury Occurring During Birth Is Called Birth Related Brachial Plexus Palsy Or Obstetric Brachial Plexus Palsy.

Key Words: Brachial Plexus , Ventral Rami , Obstetric Brachial Plexus Palsy.

Introduction

The Brachial Plexus Is The System Of Nerves That Sends Signals From Spine To Shoulder, Arm And Hand. Brachial Plexus Damage Happens When These Nerves Are Extended, Compacted, Or In The Most Genuine Cases, Tore Separated Or Torn Far From The Spinal String. It Is The System Of Nerves Which Goes Through The Cervical Spine, Neck, Axilla And Afterward Into Arm Or It Is A System Of Nerves Going Through The Cervico-Axillary Waterway To Achieve Axilla And Innervates Brachium (Upper Arm), Bet Brachium (Lower Arm) And Hand.It Is A Physical Nerve Plexus Shaped By Intercommunications Among The Ventral Rami (Roots) Of The Lower 4 Cervical Nerves (C5-C8) And The Main Thoracic Nerve (T1).Minor Brachial Plexus Wounds, Known As Stingers Or Burners, Are Regular In Contact Sports, For Example, Football. Children Some Of The Time Maintain Brachial Plexus Wounds Amid Birth[1]. Different Conditions, For Example, Aggravation Or Tumors, May Influence The Brachial Plexus.The Most Serious Brachial Plexus Wounds As A Rule Result From Auto Or Bike Mishaps. Serious Brachial Plexus Wounds Can Leave Arm Deadened, With Lost Capacity And Sensation. Surgical Methods, For Example, Nerve Unites, Nerve Exchanges Or Muscle Exchanges Can Help Reestablish Work.

Injuries To The Brachial Plexus Are Normal And Are The Most Serious Of All SoresOf Fringe Nerves. Brachial Plexus Wounds Or Injuries Can Happen Because Of Shoulder Injury, Tumors, Or Irritation. The Uncommon Parsonage-Turner Disorder Causes Brachial Plexus Aggravation Without Clear Damage However With By The By Impairing Side Effects. Brachial Plexus Sores Can Be Delegated Either Awful Or Obstetric. Obstetric Wounds May Happen From Mechanical Damage Including Shoulder Dystocia Amid Troublesome Labor. Horrendous Damage May Emerge From A Few Causes. "The Brachial Plexus Might Be Harmed By Tumbles From A Stature On To The Side Of The Head And Shoulder, Whereby The Nerves Of The Plexus Are Brutally Extended .The Brachial Plexus May Likewise Be Harmed By Coordinate Viciousness Or Discharge Wounds, By Savage Footing On The Arm, Or By Endeavors At Diminishing A Disengagement Of The Shoulder Joint"[2,3].

Function

The Brachial Plexus Is In Charge Of Cutaneous And Solid Innervation Of The Whole Upper Appendage, With Two Special Cases: The Trapezius Muscle Innervated By The Spinal Embellishment Nerve (Cn Xi) And A Territory Of Skin Close To The Axilla Innervated By The Intercostobrachial Nerve.

Clinical Anatomy

The Plexus Comprises Of Roots, Trunks, Divisions, Cords And Branches[4].

1. **Roots:** These Are Consititued By The Front Essential Rami Of Spinal Nerves C5,6,7,8 And T1 With Commitments From The Foremost Essential Rami Of C4 And T2. The Root Of The Plexus May Move One Fragment Either Upward Or Descending Bringing About A Pre Fixed Pleus Or Post Fixed Plexus Separately. Ina Prefixed Plexus, The Commitment By C4 Is Vast And In That From T2 Is Regularly Truant. In A Post Settled Plexus, The Commitment By T1 Is Substantial, T2 Is Constantly Present, C4 Is Truant, And C5 Is Decreased In Estimate. The Roots Join To Shape Trunks As Takes After:

2. Upper Trunk Is Framed By C5 And C6

Middle Trunk Is Framed By C7

Lower Trunk Is Framed By C8 And T1

3. **Divisions Of The Trunks** Each Trunk Separates Into Ventral And Dorsal Divisions (Which At Last Supply The Front And Back Parts Of The Appendage). These Divisions Join To Shape Strings.

4. **Cords**: It Frames 3 Cords

1. The Posterior Cord Is Framed From The Three Back Divisions Of The Trunks (C5-C8,T1)

2. The Lateral Cord Is The Foremost Divisions From The Upper And Center Trunks (C5-C7)

3. The Medial Cord Is Just A Continuation Of The Foremost Division Of The Lower Trunk (C8,T1).

The Different Characterisations Of Brachial Plexus Damage Are As Follows[5]:

1. Leffert Arrangement Of Brachial Plexus Damage

2. Millesi Order Of Brachial Plexus Damage

3. Classification On Anatomical Area Of Damage.

Leffert Grouping Of Brachial Plexus Damage: It Depends On Etiology And Level Of Damage And Is As Per The Following

•I Open (Ordinarily From Cutting)

•Ii Closed (Ordinarily From Bike Mishap)

•Iia Supraclavicular

•Preganglionic

•Avulsion Of Nerve Roots, Ordinarily From Rapid Wounds With Different Wounds And Loc;

•No Proximal Stump, No Neuroma Arrangement (NegTinel's)

•Pseudomeningocele, Denervation Of Neck Muscles Are Normal

•Horner’s Sign (Ptosis, Miosis, Anhydrosis)

•Postgangionic;

•Roots Stay In Place;

•Usually From Footing Wounds;

•There Are Proximal Stump And Neuroma Arrangement (PosTinel’s)

•Deep Dorsal Neck Muscles Are In Place, AndPseudomeningoceles Won’t Create;

•Infraclavicular Lesion:

•Usually Includes Branches From The Trunks (Supraclavicular);

•Function Is Influenced In View Of Trunk Included;

• Iii Radiation Actuated

•Iv Obstetric

•Iva Erb’s (Upper Root) - Server's Tip Hand;

•IvbKlumpke (Bring Down Root)

Millesi Characterization Of Brachial Plexus Damage: It Is Primarily Isolated Into 4

I: Supraganglionic/Preganglionic.

Ii: Infraganglionic/Postganglionic

Iii: Trunk.

Iv: Cord

Characterization On Anatomical Area Of Damage:

•Upper Plexus Paralysis (Erb’s Paralysis In The Obpi Cases) Includes C5-C6+/ - C7roots.

•Lower Plexus Paralysis (Klumpke’s Paralysis) Includes C8-T1 Roots (And Here And There Likewise C7)

•Total Plexus Injuries Include All Nerve Roots C5-T1

•Some Creators Have Incorporated A Fourth Kind, A Moderate Sort That Principally Includes The C7 Root.

Upper Trunk Plexus Damage

Upper-Trunk Paralysis Happens When The Edge Between The Shoulder And The Neck Persuasively Extends, For Example, When A Fall Powers The Shoulder Down And The Go To The Contrary Side.

Patients With Upper-Trunk Paralyses Can't Utilize The Shoulder To Raise The Arm Far From The Body, Have Shortcoming In The Arm, And Might Be Not Able Twist The Arm At The Elbow[6,7]. There Might Be Loss Of Sensation In The Shoulder, Outside Of The Arm, And The Thumb.

Extreme Upper-Trunk Damage May Deaden The Shoulder Muscles (Deltoid Muscle And Rotator Sleeve), And In Addition The Muscle In The Upper Arm (Biceps.)

Lower Trunk Plexus Damage

Lower-Trunk Paralysis Happens When The Edge Between The Arm And The Chest Divider Persuasively Enlarges. This May Harm The Lower Nerves And The Lower Trunks.

Patients With A Lower-Trunk Paralysis Will Commonly Keep Up Shoulder And Elbow Quality, Yet Will Lose Hand Work. After Some Time, This Will Make The Fingers Contract Into A Paw Position, And The Patient Won't Have The Capacity To Perform Fine Engine Assignments. Patients Likewise Regularly Have Hand Deadness In At Any Rate The Ring Finger And Little Finger[7].

Pan Plexus Damage

Pan Plexus Paralysis May Happen If The Power Of The Damage Is Outrageous. In Dish Plexus Paralysis, All Levels Of The Nerves And Trunk Are Harmed. This Outcomes In Entire Loss Of Motion Of The Arm And Hand, Which Is Regularly Alluded To As "Thrash Limb."[7].

Causes

Damage To The Upper Nerves That Make Up The Brachial Plexus Has A Tendency To Happen When Bear Is Constrained Down While Your Neck Extends Way Up Yonder, Into The Clouds From The Harmed Bear. The Lower Nerves Will Probably Be Harmed

When Your Arm Is Constrained Over Your Head[8]. These Wounds Can Happen In A Few Ways, Including:

•Contact Sports. Numerous Football Players Encounter Burners Or Stingers, Which Can Happen When The Nerves In The Brachial Plexus Get Extended Past Their Point Of Confinement Amid Crashes With Different Players.

•Difficult Births. Babies Can Maintain Brachial Plexus Wounds When There Are Issues Amid Birth, For Example, A Breech Introduction Or Delayed Work. On The Off Chance That A Newborn Child's Shoulders Get Wedged Inside The Birth Trench, There Is An Expanded Danger Of A Brachial Plexus Paralysis. Regularly, The Upper Nerves Are Harmed, A Condition Called Erb's Paralysis. Add Up To Brachial Plexus Birth Paralysis Happens When Both The Upper And Lower Nerves Are Harmed.

•Trauma. A Few Kinds Of Injury — Including Engine Vehicle Mischances, Bike Mishaps, Falls Or Slug Wounds — Can Bring About Brachial Plexus Wounds.

•Inflammation. Irritation May Make Harm The Brachial Plexus. An Uncommon Condition Known As Parsonage-Turner Disorder (Brachial Plexitis) Causes Brachial Plexus Aggravation With No Injury And Results In Loss Of Motion Of A Few Muscles Of The Arm.

•Tumours. Noncancerous (Kindhearted) Or Destructive Tumors Can Develop In The Brachial Plexus Or Put Weight On The Brachial Plexus Or Spread To The Nerves, Making Harm The Brachial Plexus.

•Radiation Treatment. Radiation Treatment May Make Harm The Brachial Plexus.

Signs And Symptoms

Signs And Manifestations May Incorporate A Limp Or Deadened Arm, Absence Of Muscle Control In The Arm, Hand, Or Wrist, And Absence Of Feeling Or Sensation In The Arm Or Hand. Signs And Side Effects Of Brachial Plexus Damage Can Change Enormously, Contingent Upon The Seriousness And Area Of The Damage. Normally Just A Single Arm Is Affected[9,10].

Less Extreme Wounds

Minor Harm Regularly Happens Amid Contact Sports, For Example, Football Or Wrestling, When The Brachial Plexus Nerves Get Extended Or Compacted. These Are Called Stingers Or Burners, And Can Create The Accompanying Side Effects:

•A Feeling Like An Electric Stun Or A Torching Sensation Shooting In Arm

•Numbness And Shortcoming In Arm

These Side Effects Normally Last Just A Couple Of Moments Or Minutes, However In A Few People May Wait For Quite A Long Time Or More.

Progressively Serious Wounds

Progressively Extreme Side Effects Result From Wounds That Truly Harm Or Even Tear Or Burst The Nerves. The Most Genuine Brachial Plexus Damage (Separation) Happens When The Nerve Root Is Torn From The Spinal Rope.

Signs And Side Effects Of Increasingly Serious Wounds Can Include:

•Weakness Or Failure To Utilize Certain Muscles Close By, Arm Or Shoulder

•Complete Absence Of Development And Feeling In Arm, Including Shoulder And Hand

•Severe Pain

Albeit A Few Systems Represent Brachial Plexus Wounds, The Most Widely Recognised Is Nerve Pressure Or Extend. Newborn Children, Specifically, May Endure Brachial Plexus Wounds Amid Conveyance And These Present With Run Of The Mill Examples Of Shortcoming, Contingent Upon Which Part Of The Brachial Plexus Is Included. The Most Extreme Type Of Damage Is Nerve Root Separation, Which Brings About Entire Shortcoming In Comparing Muscles. This For The Most Part Goes With High-Speed Impacts That Happens Amid Engine Vehicle Or Bike Mishaps.

Mechanism Of Injury

Genuine Plexus Wounds Are Because Of Footing On The Plexus. These Are The Aftereffect Of Joined Neck Augmentation And In Addition Ipsilateral Side Flexion And Ipsilateral Pivot. The Standard Component Of Horrible Damage Includes A Generally

Rapid Effect. This Component Causes Serious Footing Powers On The Brachial Plexus Particularly In The Upper Trunk And Can Bring About One Of Three Scenarios[11] ;

Neuropraxia

Mellow Footing Which Can Bring About A Neuropraxia Causing The " Burners And Stingers" Surely Understood And Adored In Rugby Circles. As The Name Proposes The Manifestations Are Portrayed By A Copying Or Stinging Agony Joined By Deadness, Paraesthesia And Muscle Shortcoming Normally Influencing The Entire Arm From The Upper Filaments Of The Trapezius To The Fingertips. Rehashed Neuropraxias At A Similar Level Can Bring About Huge Shortcoming Influencing The Deltoid And Biceps.

Axontmesis

Direct Power And Footing Can Bring About An Axontmesis Where There Is Disturbance Of The Axon And The Myelin Sheath With Protection Of The Sinewy Epineurium.

Neurotmesis

Neurotmesis Isn't Extremely Regular In Rugby Yet Is Seen Frequently In Engine Cycle Hustling And Is Once In A While Connected With The Noteworthy Injury To The Navigating Significant Veins, Bone Structure And Muscles.

Investigation

Clinical Examination Is Important To Recognise Dynamic Wounds To The Head, The Chest And Stomach Area. At The Point When There Is Clinical Doubt Of Harm To The Curve Of The Aorta Arteriography Is Fundamental; It Must Be Recalled That A Blade Or Rocket Does Not Regard Tissue Planes. We Have Seen An Aneurysm Of The Axillary Supply Route After Rocket Damage To The Contrary Arm And An Arteriovenous Fistula In The Back Triangle Of The Neck After A Rocket Entered The Arm And Left Underneath The Spine Of The Scapula.

Angiography, In Any Case, Isn't Generally Vital Before Critical Surgery. Honest Seeping From An Open Injury Or A Growing Swelling With Or Without A Bruit Demonstrates A Blood Vessel Damage. A Boisterous Bruit Proposes An Arteriovenous Fistula. The Clinical Determination Of Break Of The Axillary Vein In A High-Vitality

Shut Infraclavicular Sore Is Normally Direct: The Back Triangle Of The Neck Isn't Swollen, The Subclavian Heartbeat Can Be Felt, There Is An Extending Swelling Beneath The Clavicle And There Is No Brachial Heartbeat. In Such A Case Angiography Would Cause Superfluous Postponement.

Diagnosis Of The Neural Damage.

The Fundamental Component In Analysis Is The Qualification Amongst Pre-And Postganglionic Sores. In Preganglionic Burst, The Afferent Nerve Filaments With Cell Bodies In The Dorsal Root Ganglion Don't Degener-Ate. Just Efferent Strands To Skeletal Or Smooth Muscle Experience Wallerian Degeneration. It Is Presently Of More Than Scholastic Intrigue That A Preganglionic Or Intradural Sore Is Analyzed All The More Precisely As Either A Crack Of The Rootlet Fringe To The Focal Fringe Transmission Zone (Bert-Hold, Carlstedt And Corneliuson 1993) Or A Genuine Separation From The Spinal String, Which Is Damage To The Focal Apprehensive System[12]. Up To This Point, This Refinement Could Be Made Just By Investigation Of The String Or Histological Examination Of The Tips Of Separated Rootlets, Yet It Is Likely That Upgrades In Mri Systems Will Make The Finding Conceivable.

An Exact History And Physical Examination Permit A Neurological Finding As A Rule. The Relative Brutality Of The Damage And Gauge Of The Power Connected To The Appendage Are Especially Significant[13,14,15]. The Trademark Torment From A Preganglionic Damage Begins On The Main Day In Around Half Of Cases; The Patients Depict A Steady Pounding Or Consuming Agony In The Hand With Superimposed 'Lightning Stuns' Shooting Down The Appendage. Direct Scraped Spots From The Neck To The Shoulder, Swelling In The Back Triangle And Vascular Damage All Propose That A Savage Footing Power Has Been Connected.

The Degree Of Nerve Harm Is Effortlessly Learned By The Individuals Who Have Contemplated The Mrc Notice Aids To Examination Of The Fringe Sensory System (1976); All Specialists Treating Wounds Ought To Be Comfortable With This Work[16]. Assurance Of The Level Of The Injury, Regardless Of Whether It Is Intradural Or A Postganglionic Crack, Is More Troublesome, Yet Entire Thoughtful Loss Of Motion Is An Indication Of Break. Pre-Ganglionic Damage Of The Upper Three Foundations Of The Plexus Is Proposed By Loss Of Sensation Over The Clavicle, With Loss Of Motion

Of The IpsilateralHemidiaphragm, Serratus Foremost And Trapezius; A Bernard-Horner Sign Shows Comparative Damage To The Lower Two Roots[17]. An Unequivocally Positive Tinel Sign Proposes A Postganglionic Crack. Percussion Of The Back Triangle Of The Neck Makes The Patient Feel Sticks And Needles Transmitting To The Elbow When The Fifth Cervical Nerve Has Been So Harmed; If These Sensations Reach Out To The Thumb And Forefinger, At That Point The 6th Cervical Nerve Has Been Harmed. Plain Radiographs Of The Neck And The Chest Are Constantly Valuable. Tilting Of The Cervical Spine Far From The Side Of Damage Is Suggestive Of Finish Intradural Damage; Breaks Of The Transverse Procedure Of C7 Or Of The Principal Rib May Show Intradural Damage Of The Lower Two Roots. Variety In The Life Structures Of The Brachial Plexus Is A Noteworthy Trap In Clinical Conclusion. It Isn't Exceptional To Locate The Advanced Extensors Innervated By The Primary Thoracic Nerve; On The Other Hand, Numerous Patients With In Place C8 And T1 Have Loss Of Motion Of All Extensor Muscles. 'Pre' And 'Post' Obsession Of The Plexus Is Once In A While Critical.

Advanced Examinations

Physiological Analysis Depends On Bonney's Finding That Afferent Axons Stay Myelinated On The Off Chance That They Are Still In Progression With The Dorsal Root Ganglion. In The Event That Intradermal Histamine Prompts A Flare In Soporific Skin Then The Spinal Nerve Providing That Skin Has Been Separated From The Spinal String. On The Off Chance That A Tactile Activity Potential Can Be Recorded From The Incitement Of A Sedative Forefinger Then The 6th Cervical Nerve Has Been Harmed Along These Lines. These Examinations Are Valuable Simply After Wallerian Degeneration Has Occurred, No Less Than Three Weeks After Injury[18,19]. Early Myelography, Inside A Couple Of Days Of Damage, Might Be Hard To Decipher When There Has Been A Tear Of The Dura, Yet A Decent Quality Myelogram Is To A Great Degree Valuable After Around Seven Days And Surprisingly Better When Joined With Ct. The Show Of Evoked Possibilities From Scalp Cathodes By The Incitement Of Uncovered Spinal Nerves Prohibits Separation. Kline (1989) Has Demonstrated The Estimation Of Intraoperative Nerve Activity Possibilities In The Analysis Of Sores In Progression, Outstandingly Those Caused By Discharge Injuries[20].

Mri Is Important In Showing Sores Of The Spinal String And Of Damage Inside The Back Triangle. It Can Recognise Denervated, Incompletely Denervated And Innervated

Muscle (Fleckenstein Et Al 1993)[21]. Francel Et Al (1995) Have Stretched Out Its Utilization To The Determination Of Birth Injuries Of The Brachial Plexus[22].

Treatment

Treatment For Brachial Plexus Wounds Incorporates Orthosis/Supporting, Word Related Or Exercise Based Recuperation And, At Times, Surgery. Some Brachial Plexus Wounds May Recuperate Without Treatment. Numerous Newborn Children Enhance Or Recuperate Inside A Half Year, However Those That Don't Have An Extremely Poor Viewpoint And Will Require Assist Surgery To Endeavor To Adjust For The Nerve Shortfalls. The Capacity To Twist The Elbow (Biceps Work) By The Third Month Of Life Is Viewed As A Pointer Of Plausible Recuperation, With Extra Upward Development Of The Wrist, And Also Rectifying Of Thumb And Fingers A Considerably More Grounded Marker Of Superb Unconstrained Change. Delicate Scope Of Movement Practices Performed By Guardians, Joined By Rehashed Examinations By A Doctor, Might Be All That Is Important For Patients With Solid Markers Of Recuperation.

Comprehensively Surgery For These Is Separated In Two General Classes:

•Surgery For Nerve Repair

•Secondary Methodology

At Whatever Point Practical Relying Upon Timing, Surgery For Nerve Repair Outweighs Every Other Methodology Since Time Is Of The Embodiment. When Different Wounds Are Managed Essentially The Patient Ought To Have The Soonest Conceivable Nerve Repair.

Optional Techniques Are Done After Nerve Repairs Or In Late Cases As A Substitute To Reestablish Work. Whichever Way All Patients Can Be Offered Some Treatment At All Stages.

Surgery For Nerve:

Extensively Arranged In To:

•Intra Plexus Repair

•Extra Plexus Repair

•Distal Nerve Exchanges

•Contralateral C7 Exchange.

Frequently A Mix Of These Might Be Advertised.

Intra Plexal Repair

In Instances Of Post Ganglionic Damage Where Contributor Roots Are Accessible, The Root Stumps Are Joined To Distal Targets Which Might Be Trunks, Ropes Or Individual Nerves With The Assistance Of Autologous Nerve Unites. These Might Be Free Joins Or Vascularised Unites. As A Rule Short Joins Improve The Situation Than Long Unites; Notwithstanding, Such A Decision Isn't Generally Accessible.

Extra Plexal Repair

Nerves Not Emerging From The Plexus Are Utilized As Giver Nerves. Great Case As Being, Intercostal Nerves (Icn) To Musculo Cutaneous Nerve (Mcn) For Biceps And Spinal Accessory Nerve (San) To Supra Scapular Nerve (Ssn) For Rotator Sleeve Reinnervation. A Few Creators Utilize Phrenic Nerve. Despite The Fact That They Guarantee That All Parameters Continuously Recoup To Preoperative Status Levels Inside 1 Year; The Loss Of Stomach Work Prevents Numerous Others From Utilizing It. Bhandari Et Al Have Demonstrated That However The Phrenic Exchange Produces The Coveted Engine Result, The Long Haul Follow Up Of The Patients Demonstrated A Relentless Pneumonic Capacity Shortage Even Toward The Finish Of Quite A Long While In Extremely Fit Youthful Adults[23]. Their Information And Conclusions Are Repeated Beneath.

Methodologies For Recreation

Methodologies For Grown-Ups And Kids (Birth Brachial Plexus Injury Bbpi) Vary Extensively. The Creator Has Examined The Bbpi Systems Somewhere Else In Detail. Youngsters Have A Far More Prominent Recovery Limit And Separation To Movement

For The Recovering Axons Is Far Littler. Hence Conceivably Add Up To Recreation Up To And Including The Hand Inborn Muscles Is Possible Even In An Every One Of The 5 Root Damage If Worked In Time[24]. This Is Once In A While Doable In A Grown-Up Add Up To Paralysis.

Conclusion

The Vital Advances Of The Most Recent 30 Years Include: Refinement Of Conclusion; Re-Learning And Re-Use Of The Standards Of The Treatment Of Wounds And Vascular Injuries; Enhanced Strategies For Nerve Repair And Exchange; And, In Particular, An Approach Of Earnest Investigation And Repair. Great Useful Recuperation Can Sensibly Be Normal In Patients With Either Pre-Or Postganglionic Harm To The Fifth, 6th And Seventh Cervical Nerves, And In Place Eighth Cervical And First Thoracic Nerve. On The Off Chance That Specialists Repudiate The Destructive Strategy Of Delaying Most Patients Can Accomplish Rebuilding OfThoracoscapular Control, Glenohumeral Control, Elbow Flexion And Wrist Expansion, With Ordinary Sensation Inside The Middle Domain Of The Hand And The Help Of Torment. Because Of The Expansive Range Of Brachial Plexus Wounds, It Is Hard To Gauge The Rate Of Unconstrained Recuperation. The Potential For Unconstrained Recuperation Relies Upon The Sort And Seriousness Of Damage. In This Way, Visualization Must Be Surveyed For Every Patient Separately In View Of The Sort And Seriousness Of Their Damage, And The Movement Of Any Unconstrained Recuperation That Might Be Occurring.Depending On The Level Of Seriousness, Some Nerve Wounds Can Mend Without Anyone Else. On The Off Chance That This Isn't A Feasible Alternative For A Specific Patient, A Surgical Choice Might Be Prescribed By The Doctor. Physical Restoration Treatment Is Dependably Part Of The Recuperation Procedure For A Brachial Plexus Injury.The Level Of Practical Weakness And Potential For Recuperation Rely Upon The System, Type, Intricacy Of The Brachial Plexus Damage, And Time From Damage. The Most Imperative Choice Your Specialists Will Make Is Deciding Whether And When Surgical Mediation Ought To Happen.

Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstract

Bruxism is an oral parafunctional habit prevalent in all age groups which is characterized by the involuntary teeth grinding or clenching that may occur at any time of the day. It has a multifactorial aetiology associated with occlusal and psychological factors and habits that can compromise the orthognathic system that may bring negative consequences. Bruxism can be classified as awake or sleep bruxism. Patients with sleep bruxism are more likely to experience jaw pain and limitation of movement, than people who do not experience sleep bruxism. Faulty occlusion is one of the most common causes of bruxism that further leads to temporomandibular joint pain. This review focuses upon various aspects of bruxism and its treatment modalities.

Key Words: *Tooth grinding, Wear facets, Malocclusion, Temporomandibular disorders, Muscle fatigue*

Introduction

Bruxism has been considered a detrimental motor activity known to potentially cause over activity of the stomatognathic structures.Tooth grinding (bruxism) has been of prime importance to dentist as it leads to significant tooth damage, breakage of dental restorations, induction of temporal headache, temporomandibular disorders and orofacial muscle fatigue [1].Activities of the masticatory system can be divided as Functional and Parafunctional. Function includes chewing, speaking and parafunctionalincludes clenching or grinding of the teeth (referred to as bruxism). Parafunctional activity oftenleads muscle hyperactivity. The functional activities are very controlled muscle activities, which allow the masticatory system to perform necessary functions with minimum damage to the structures of this system. These functions are often disturbed by interfering tooth contact leading to inhibition of functional muscle activity. Therefore, functional activities are considered to be directly influenced by the occlusion.

The term parafunction was introduced by Drum [2] to suggest distinction between occlusal stress exerted during mastication and swallowing and occlusal stress which are brought into action outside of the normal function. Parafunctional activities are non functionaloromandibular or lingual activities that includes jaw clenching, bruxism, tooth grinding, tooth tapping, cheek biting lip biting, object biting etc. that can occur alone or in combination and are different from functional activities like chewing, speaking and swallowing.

The term ‘la bruxomanie’ was first introduced by Marie Pietkiewicz in 1907 [3]. It was latter adopted as ‘bruxism’ to describe gnashing and grinding of the teeth occurring without a functional purpose. Glossary of Prosthodontic Terms (GPT-8) [4] defines bruxism as parafunctional grinding of teeth or an oral habit consisting of involuntary rhythmic or spasmodic non functional gnashing, grinding or clenching of teeth in other than chewing movements of the mandible which may lead to occlusal trauma. Bruxism can occur during wakefulness or during sleep. Bruxism during daytime is commonly a semivoluntary ‘clenching’ activity and is also known as ‘Awake Bruxism’ (AB) or Diurnal Bruxism (DB). AB can be associated with life stress caused by familial responsibility or work pressure. Bruxism during sleep either during daytime or during night is termed as ‘Sleep Bruxism’ (SB). SB is an oromandibular behaviour that is defined as a stereotyped movement disorder occurring during sleep and characterized by tooth grinding and/or clenching [5]. Sleep

bruxism was recently classified as sleep related movement disorder according to recent classification of Sleep Disorders. Historically, occlusal/articulation and skeletal factors were believed to constitute the greatest risk for bruxism, but modern studies have failed to demonstrate a consistently significant relationship between such factors and bruxism. Factors which have been implicated as having an increased risk for bruxism include lower age, female gender, tobacco, alcohol and caffeine usage, psychosocial factors (e.g. stress and anxiety), sleeping disorders (e.g. obstructive sleep apnea), genetics and certain medications or drugs. Some authors have emphasized that bruxism during sleep and during wakefulness should be regarded as two separate entities, probably with different etiologies, and with different presumed risk factors. The American Academy of Sleeping Disorders proposed the terms sleep and awake bruxism [3]. Even though most of the literature does not differentiate between sleep and awake bruxism, studies in sleep-laboratories are thought to produce research of higher quality (sometimes called the ‘‘gold standard’’) than other types of studies, many of which are based on self-reports. It follows that self-report is not an adequate measure of sleep bruxism because of diagnostic bias and confounders. At the practical level, however, the process of diagnosing sleep bruxism by means of polysomnography (PSG) is complicated, while detecting awake bruxism is easier as the patient can report it after becoming, or being made aware of the habit. However, there are some promising recent developments in portable EMG measuring devices for diagnosing bruxism which correlate well with the gold standard, viz. PSG [5].

Prevalence rate of AB and SB is about 20 and 8–16% respectively in adult population [6]. AB is found to occur predominantly among females while no such gender difference is seen for sleep bruxism [7]. Onset of SB is about 1 year of age soon after the eruption of deciduous incisors [8]. The disorder is appearing more frequently in the younger population. The prevalence in children is between 14 to 20%. In adults aged above 60 years and over only 3% are being aware of frequent grinding [9].

Most of the functional activity of mandible occurs at or near the centric occlusion position. The forces related to the functional activity are distributed to many teeth that minimize potential damage to a single tooth. Bruxism occurs in eccentric positions. Few tooth contacts occur during the activity and in this activity, the mandibular position is far from its stable position. This position of mandible causes more strain on the masticatory system, making it more susceptible to breakdown. This causes the application of heavy forces to a few teeth

[10]. This review aims on enumerating the various methods of detecting bruxism and its treatment options.

Aetiology

Bruxism is considered to have multifactorial aetiology. Sleep Bruxism and grinding have been associated with peripheral factors such as tooth interference in dental occlusion, psychosocial influences such as stress or anxiety and central or pathophysiological causes involving brain neurotransmitters or basal ganglia [11].

Central or Pathophysiological Factors

More and more pathophysiological factors are suggested to be involved in the precipitation of bruxism. As the bruxism often occurs during sleep, the physiology of sleep has been studied extensively especially the ‘arousal response’ in search of possible causes of disorder. Arousal response is a sudden change in the depth of the sleep during which the individual either arrives in the lighter sleep stage or actually wakes up. Such a response is accompanied by gross body movements, increased heart rate, respiratory changes and increased muscle activity. Macaluso et al in their study showed 86% of bruxism episodes were associated with arousal response along with involuntary leg movements. This shows that bruxism is a part of arousal response indeed [12].

Recently it is derived that disturbances in central neurotransmitter system may be involved in the aetiology of the bruxism [13]. It is hypothesized that the direct and indirect pathways of the basal ganglion, a group of five sub cortical nuclei that are involved in the coordination of movements is disturbed in bruxer. The direct output pathway goes directly from the stratum to the thalamus from where afferent signals project to the cerebral cortex. The indirect pathway on the other hand passes by several other nuclei before reaching it to the thalamus [14]. If there is imbalance between both the pathways, movement disorder results like Parkinson’s disease. The imbalance occurs with the disturbances in the dopamine mediated transmission of action potential. In case of bruxism there may be an imbalance in both the pathways. Acute use of dopamine precursors like L-dopa inhibits bruxism activityand chronic long term use of L-dopa results in increased bruxism activity. SSRTs (serotonin reuptake inhibitors) which exert an indirect influence on the dopaminergic system may cause bruxism after long term use [13]. Amphetamine which increases the dopamine concentration by facilitating its release has been observed to increase bruxism. Nicotine stimulates central

dopaminergic activities which might explain the finding that cigarette smokers report bruxism two times more than the non smokers [15].

Psychosocial Factors

Number of studies is published in the literature regarding the role of psychosocial factors in the aetiology of bruxism but none of these describe the conclusive nature because of the absence of large scale longitudinal trials. Bruxers differs from healthy individuals in the presence of depression, increased levels of hostility and stress sensitivity. Bruxing children are more anxious than non bruxers. A multifactorial large scale population study to sleep bruxism revealed highly stressful life as a significant risk factor [16]. A study by Van Selms et al demonstrated that daytime time clenching could significantly be explained by experienced stress, although experienced stress and anticipated stress were unrelated to sleep bruxism as recorded with ambulatory devices [17]. All these studies show possible relationship between bruxism and various psychosocial factors are growing but not conclusive.

Peripheral Factors

Several occlusal factors were suggested to be related to self reported bruxism in a study with children. Giffin in his article has mentioned that for an effective management of bruxism, establishment of harmony between maximum intercuspation and centric relation is required [18]. But most of studies published in the literature on this subject now agree that there is no or hardly any relationship between clinically established bruxism and occlusal factors in adults [19]. Manfredini et alin their review of literature have stated that there is still a lack of methodological sound studies to definitely refute the importance of occlusal factors in the etiology of bruxism. [20]

Clinical Diagnosis

Its diagnosis and clinical evaluation is complex, because both bruxers and normal individuals may show some nocturnal parafunctional activity. Diagnosis must be focused on identifying the signs and symptoms reported by the patient or by the dentist over the clinical examination [21]. Dental enamel is the first structure affected from the parafunctional load and abnormal wear of the teeth is the most common evidence of this condition. It may be restricted to a single tooth or the entire mouth [22]. Radiographic examination can show the loss of the

lamina dura, changes in the periodontal space, which can either disappear or be increased, root resorption, root fractures and pulp stones. The major lesions caused by bruxism can be gathered as: effects on teeth, periodontium, masticatory muscles and TMJ, headaches, behavioral and psychological effects. Other signs and symptoms are parafunctionalhyper mobility in the absence of periodontal disease, pulpitis, toothache (with normal pulp), partial crown fractures and teeth migration. Muscular symptoms include fatigue, increased tension in masticatory muscles, especially the lateral pterygoid muscle, mandibular elevator muscles, masseter and temporal [23]. The most common muscular symptom is fatigue, which is the inability to resist during a sustained effort without having apparent signs and symptoms of pain and discomfort [24]. Bruxism can also cause posture problems. In addition, it can affect masticatory muscles and postural muscles of the cervical spine, which may cause muscular pain and future chronic permanent changes. Bruxism harmful habit causes relevant changes in the stomatognathic system structure. It causes friction, inflammation, pulpal necrosis and teeth mobility. It may occur muscle pain and tenderness to palpation and TMJ pain and noises due to lack of coordination of the lateral pterygoid muscles or alter the articular heads, as well as the vertical dimension loss and mandibular displacement in maximal intercuspal position (MIP) [25].

Detection of Bruxism

Intraoral Appliance

Bruxism activity can be evaluated using the intra-oral appliance and is classified into two groups observation of wear facets of the intra-oral appliance and measurement of bite force loaded on the intra-oral appliance.

Wear Facets of Intra-oral Appliance

Holmgren et al. reported a repetitive wear pattern on the occlusal splint. They observed wear facets on full-arch acrylic resin splints, which reappeared in the same location with a similar pattern and direction, even after adjustment of the splints. Also, Korioth et al. reported that parafunctional nocturnal dental activity on full-arch occlusal stabilization splints resulted in wear, which was both asymmetric and uneven. Unfortunately, no confirmation of the reliability of these methods has been reported. [26]

Bruxcore Plate

The Bruxcore Bruxism-Monitoring Device (BBMD) is an intra-oral appliance that was introduced as a device for measuring sleep bruxism activity objectively [27] and the Bruxcore plate evaluates bruxism activity by counting the number of abraded microdots on its surface and by scoring the volumetric magnitude of abrasion. The BBMD is a 0.51-mm-thick polyvinyl chloride plate that consists of four layers with two alternating colours and a halftone dot screen on the topmost surface. The number of missing microdots is counted to assess the abraded area and the number of layers uncovered represents the depth parameter. Both parameters are combined to obtain an index for the amount of bruxism activity. The major disadvantage with this method is that it is difficult to count the number of missing dots with good precision. Pieree and Gale [27] in their study did not find any significant co relation between the duration of bruxism analyzed with the EMG data and that with the bruxcore plate scores. In this respect, the bruxism activity assessed by Bruxcore plates may not be the same as that measured with a portable EMG device. However, the relationship between wear and bruxism activity is still questionable [28].

Detection of Bite Force

Takeuchi et al developed a recording device for sleep bruxism, an intra-splint force detector (ISFD), which uses an intra-oral appliance to measure the force being produced by tooth contact onto the appliance. The force is detected using a thin, deformation-sensitive piezoelectric film, which is embedded 1–2 mm below the occlusal surface of the appliance. It was confirmed that the duration of bruxism events during simulated bruxism, i.e. clenching, grinding, tapping and rhythmic clenching, evaluated with the ISFD was correlated with that of the masseter EMG [29]. Even though the ISFD did not correctly capture force magnitudes during sustained clenching because of the characteristic of the piezoelectric film, i.e. this transducer is best at detecting rapid changes in force, not static forces. ISFD was not suitable for detecting the magnitude of force during steady-state clenching behaviour.

It is obvious; however, that the major problem of these methods is that subjects have to wear the intra-oral device and this may change the original bruxism activity. Well-designed comparative studies with polysomnographic recordings are required to evaluate the possible influences of the intra-oral device on the original bruxism activity [30].

Masticatory Muscle Electromyographic Recording

Among the various methods for the assessment of bruxism, the EMG recording has been commonly used to measure actual sleep bruxism activity directly. The principal advantage is that the occurrence of bruxism can be assessed without intra-oral devices, which may change natural bruxism activity.

Portable EMG Recording Device

Starting in the 1970s, sleep bruxism episodes were measured over an extended period in patients homes with the use of battery-operated EMG recording devices. The portable EMG recording system has become easy for subjects to operate and can measure masticatory muscle activity more minutely, i.e. the number, duration and magnitude of bruxism events can be evaluated with fair accuracy. Criteria for the detection of sleep bruxism with the portable EMG recording system have been suggested [31] but their validity in a large population has not yet been confirmed.

The detection power of sleep bruxism is generally considered inferior to that in a sleep laboratory because other confounding oro-facial activities (e.g. sight, coughing and talking) cannot be discriminated from sleep bruxism. Also, other sleep disorders cannot be ruled out or other physiological changes related to sleep bruxism (e.g. microarousal, tachycardia and sleep-stage shift) cannot be monitored. The implement for recording the heart rate was recommended as one of the compensatory measures for improving the accuracy of sleep bruxism recognition. Also, a surface EMG electrode with a built-in buffer-amplifier and a cordless type of EMG measurement system was developed to improve the reliability of recordings [32].

Miniature Self-Contained EMG Detector–Analyser

A miniature self-contained EMG detector–analyser (BiteStrip) was developed as a screening test for moderate to high level bruxers[33]. The device, which is comprised of EMG electrodes, an amplifier, a central processing unit (CPU) with software, a display which presents the outcome in the morning, a light emitting diode and a lithium battery records the number of masseter muscle activities above a preset threshold. The special feature of this device is that the number of bruxism events can be objectively estimated by simply attaching it to the skin over the masseter muscle. Minakuchi and Clark examined the sensitivity and specificity of the BiteStrip recording versus masseter EMG recordings during a polysomnogram in five suspected bruxers. Overall, there was good specificity for all subjects

but fair sensitivity for subjects that exhibit moderate to high levels of EMG determined bruxism. The device might be a cost-effective tool for screening moderate- to high level bruxism subjects. [34]

More recently, a miniature self-contained EMG detector–analyser with a biofeedback function (Grindcare) was developed as a detector and biofeedback device for sleep bruxism. It is comprised of EMG and stimulation electrodes, a microprocessor, a memory for data storage, a display for user interface, light-emitting diodes, a rechargeable battery, a plug-in USB connector for data connection to computer to a battery charger, and a strap for carrying the apparatus around the forehead. It enables the online recording of EMG activity of the anterior temporalis muscle, online processing of EMG signals to detect tooth grinding and clenching and also biofeedback stimulation for reducing sleep bruxism activities. Although scientific confirmation is needed for a large population, it is considered as one of the potent devices for detecting and also for managing sleep bruxism. The portable EMG recording system enables multiple-night recording in a natural environment for the subject with minimal expense.

Finally, a miniature self-contained EMG detector–analyser seems to be a potentially useful device for detecting sleep bruxism. Polysomnographic (sleep laboratory) recordings for sleep bruxism generally include electroencephalogram, EMG, electrocardiogram and thermally sensitive resistor (monitoring air flow) signals along with simultaneous audio–video recordings. Sleep bruxism activity is assessed based on EMG activity in the masticatory muscles (masseter and/or temporalis). Because the sleep laboratory setting offers a highly controlled recording environment, other sleep disorders (e.g. sleep apnoea and insomnia) can be ruled out and sleep bruxism can be discriminated from other orofacial activities (e.g. myclonus, swallowing and coughing) that occur during sleep [35]. Physiological changes related to sleep bruxism (e.g. microarousal, tachycardia and sleep-stage shift) can also be monitored. Hence, a polysomnographic study allows for multidimensional analyses of sleep-related physiological behaviours and studies on sleep laboratory EMG-based assessments are reported to be very reliable. One major limitation is that a change in the environment for sleep may influence the actual behaviour of bruxism. Another is the expense as multiple night recording is to be taken for the occurrence of sleep bruxism varies over a number of nights [36].

Management of Bruxism

Depending on the etiology, signs observed during the clinical examination and symptoms described by patients, the treatment changes. Furthermore, it is important to make a differential diagnosis [37]. Treatment demands a multidisciplinary approach, involving Psychology, Physiotherapy and Speech Therapy, having in consideration oral, medical and psychological aspects of the patient [38]. Treatment plan should attend the following objectives: physical and psychological stress reduction, treatment of signs and symptoms, reduce occlusal interferences and change the patient's usual neuromuscular pattern. The starting point for treatment aims to decrease psychological stress using relaxation exercises, massage and physiotherapy [39]. This treatment reduces the symptoms but not the cause. The habit may restart whenever the patient's tolerance regarding an occlusal change decreases [40]. Specific treatment for muscle pain is based on methods that disrupt mechanisms of pain cycle, as myofascial trigger point therapy (cool mist spray), anesthetic block in association with physiotherapy techniques such as exercise to restore function and deep heat massage. Occlusal therapy may include occlusal adjustment. Although occlusal condition exerts minor influence on the process, occlusal adjustment, irreversible therapeutic method, is suitable to minimize damages caused by teeth grinding but not for treating bruxism [37]. The use of interocclusal splints reduces symptoms, even if it has not stopped bruxism, because they act in TMJ, inducing the condyle to stand correctly in the condylar fossa. The distribution of masticatory forces is responsible for the relief of symptoms [40]. The splints may differ in material, rigid or resilient, and in structure, thickness and occlusal coverage extension. Thus, according to therapeutics indication, the splits may set different intermaxillary relations [38]. Depending on the complexity of the case, it is usually recommended its use at night, for 45 days, with weekly maintenance. Despite its etiology, occlusal therapy can always be suitable, because it promotes functional comfort, preventing further damage to the components of the masticatory apparatus. Biofeedback is based on the principle that bruxers can 'unlearn' their behaviour when a stimulus makes them aware of their adverse jaw muscle activities ('aversive conditioning'). This technique has been applied for bruxism during wakefulness as well as for sleep bruxism. While awake, patients can be trained to control their jaw muscle activities through auditory or visual feedback from a surface EMG. For sleep bruxism, auditory, electrical, vibratory and even taste stimuli can be used for feedback. Pharmacological treatment with drugs such as dopamine agonists, anxiolytics, buspirone,

nonbenzodiazepines hypnotics, antiepileptic and botulinum toxin, is appropriate when bruxism is intense[41].

Conclusion

Bruxism is a common parafunctional habit, occurring both during sleep and wakefulness, and sleep bruxism and awake bruxism should be differentiated. The etiology of bruxism is not well known can be agreed that it is multifactorial. There is no specific treatment available at this time to stop bruxism and hence we should focus on various methods to reduce the adverse effects of the habit. Early detection using various methods is of prime importance. The use of interocclusal appliances is the most common and accepted way to prevent wear of teeth and prosthodontic restorations in spite of lack of strong evidence for its efficacy. The role of bruxism in the multifactorial process of tooth wear is not clear, but it is in general not the major cause, as has been a frequently stated earlier literature. In extensive tooth wear, the decision to treat or not should be based on the patient's perceived need, the severity of the wear and risk of its progression with respect to the patient's age. When prosthetic intervention is indicated in a patient with bruxism, efforts should be made to reduce the effects of heavy occlusal loading on all the components that contribute to prosthetic structural integrity. Therefore, a multi disciplinary approach is steered towards attempting to prevent damage and to treat the pathological effects of bruxism on the structures of the stomatomasticatory system.

Abstract

Burkitt's lymphoma is a highly aggressive B-cell non-Hodgkin lymphoma and is the fastest growing human tumour. The disease is associated with Epstein-Barr virus and was one of the first tumours shown to have a chromosomal translocation that activates an oncogene (c-MYC). Burkitt's lymphoma is the most common childhood cancer in areas where malaria is holoendemic. The incidence is very high in immunosuppressed patients in non-endemic areas, especially when associated with HIV infection. Outcome with intensive chemotherapy has improved and is now excellent in children, but the prognosis is poor in elderly adults. The success of intensive treatment relies on good supportive care. The therapy offered in oncology units in low-income countries is not as aggressive as in centres in high-income countries and outcomes are less successful. Adjuvant monoclonal antibody therapy with rituximab shows promise for improved outcomes and reduced toxic effects in the future.

Key Words: Burkitt's lymphoma, Malaria, Histopathology, Prognostic Markers, Tumours

Introduction

Burkitt's lymphoma has had an important role in the understanding of tumorigenesis. It was the first human tumour to be associated with a virus,[1] one of the first tumours shown to have a chromosomal translocation that activates an oncogene,[2,3] and the first lymphoma reported to be associated with HIV infection[4]. Burkitt's lymphoma is the fastest growing human tumour, with a cell doubling time of 24–48 h, and was the first childhood tumour to respond to chemotherapy alone [5].It is the most common childhood cancer in areas where malaria is holoendemic—e.g., equatorial Africa, Brazil, and Papua New Guinea.6 The so-called Burkitt's lymphoma belt stretches across central Africa 15° either side of the equator where the climate is hot and wet (more than 50 cm annual rainfall). The epidemiological maps of malaria and Burkitt's lymphoma overlap [5–7].

Early in the 20th century, Sir Albert Cook, a missionary doctor in Uganda, and other medical staff working in west, east, and central Africa noted the high frequency of jaw tumours and childhood lymphomas [8–10]. In 1958, Denis Burkitt, an Irish surgeon working in Uganda, reported cases of children presenting with rapidly growing jaw or abdominal tumours [11]. Burkitt suggested that these tumours were round-cell sarcoma. However, in 1960 George O'Connor, a pathologist, concluded that the cancer was of lymphoma lineage [12]. In 1964, three virologists, Michael Anthony Epstein, Yvonne Barr, and Bert Achong identified viral particles in the tumour tissue; this virus became known as Epstein-Barr virus (EBV) [1]. Meanwhile, Burkitt travelled through eastern and central Africa to map the tumour spread and found records of affected children in all the malarial areas of the region [13].

Classification

The WHO classification of Burkitt's lymphoma de- scribes three clinical variants: endemic, sporadic (the predominant type found in non-malarial areas), and immunodeficiency-related [20]. These types are similar in morphology, immunophenotype, and genetic features.

The endemic variant is associated with malaria endemicity and EBV is found in almost all cases. The sporadic type occurs mainly throughout the rest of the world (predominantly North America and Europe), with no special climatic or geographical links, and is rarely associated with EBV infection. 1–2% of adult lymphomas and 30–40% of childhood non-Hodgkin lymphomas in Europe and North America are sporadic-type Burkitt's lymphoma [21]. The immunodeficiency-related type is seen most often in patients with HIV infection and less

than 40% of US and European cases are associated with EBV. Before the advent of antiretroviral therapy in North America the disorder was 1000 times more common in HIV-positive people than in uninfected individuals [22, 23]. Immunodeficiency-related Burkitt's lymphoma is more common when the CD4 T-cell count is greater than 200 per μL (early in the progression of HIV infection). The association of HIV with Burkitt's lymphoma is not as clear in the endemic form [24]. The risk of BL increases 4 to 5 years after organ transplantation, but this risk is much less than that associated with HIV infection [25].

Epidemiology

The distribution of endemic Burkitt's lymphoma across Africa and Papua New Guinea corresponds to areas of holoendemic malaria and the early acquisition of EBV [13,26–32]. The annual incidence has been estimated at 40–50 per million children younger than 18 years [33]. In these high-risk areas endemic Burkitt's lymphoma comprises about half of all childhood cancer diagnoses and up to 90% of lymphoma diagnoses. Incidence peaks at age 6 years and the disease is twice as common in boys as in girls. Sporadic Burkitt's lymphoma occurs most commonly in children aged 3–12 years (median 6–8 years) and is 3·5 times more common in boys than in girls [34,35].

Sporadic Burkitt's lymphoma is found in low-risk areas such as North America, northern and Eastern Europe, and East Asia at an annual incidence of 2 per million children younger than 18 years. Parts of South America, southern Europe, North Africa, and the Middle East are areas of intermediate risk [30]. Immunodeficiency-associated Burkitt's lymphoma occurs at an incidence of 22 per 100 000 person-years in the USA [36].

Cofactors

Epstein-Barr virus

Several observations suggest a direct causative role for EBV in endemic Burkitt's lymphoma. For example, EBV is consistently present in these tumours; [37] infection of malignant B cells precedes tumorigenesis; [38] EBV induces immortalisation of B cells in culture; and very high EBV antibody titres are recorded in children before development of the disease [39]. However, the underlying mechanism linking EBV infection of B cells to the emergence of malignancy remains undiscovered.

Although EBV encodes several latent proteins essential for viral immortalisation of B cells,[40–42] EBNA1 protein is the only EBV latent protein consistently expressed in endemic Burkitt's lymphoma tumours. Other EBV latent and lytic transcripts are also detected in some tumours (figure 2),[37,44] but only in a subset of cells. Tumours containing a deletion of the EBNA2 gene have been identified, which leads to expression of EBNA3A, EBNA3B, and EBNA3C genes [46]. Cell lines derived from these lymphomas are resistant to apoptosis, which suggests that loss of EBNA2 provides a survival advantage to the tumour [47]. One function of EBV in endemic Burkitt's lymphoma might be to block apoptosis in B cells with an MYC translocation through either the EBNA1 protein, the BHRF1 protein, EBER transcripts, or epigenetic modification and subsequent repression of the pro- apoptotic BIM protein by the latent transcript LMP1 [48,49]. EBV can also promote genomic instability, deregulate telomere functions, and induce DNA damage to infected cells.50 Viral microRNAs have been identified in EBV- positive endemic and AIDS-associated Burkitt's lymphomas,[45] and are thus also potential candidates for driving tumorigenesis.

The cell type of origin of the Burkitt's lymphoma cell is controversial; some have argued that the tumour arises from a germinal centre B cell, [51] whereas others believe that it originates from a memory B cell [52]. This question is also relevant to the role of EBV in endemic disease. EBV persists for the lifetime of the healthy host as a latent infection in peripheral memory B cells. If the malignant cell arises from a latently infected cell and cycling memory B cells express only EBNA1 (similar to endemic Burkitt's lymphoma), [53] the latently infected memory B cell could be the source of the malignancy.

EBV can be identified in almost all endemic Burkitt's lymphomas, but is reported less frequently in the other types, which raises the question of whether EBV is a requirement for pathogenesis. The absence of EBV in other types of Burkitt's lymphoma might result from loss of viral episomes from tumour cells after cell division. EBV-positive Burkitt's lymphoma has a higher frequency than EBV-negative disease of somatic mutations in the immunoglobulin variable heavy chain with evidence of antigen selection. A possible explanation for this findingis that EBV-positive Burkitt's lymphoma arises from memory cells whereas EBV-negative disease originates from an earlier germinal centre counterpart [54].

Malaria

In Africa, pronounced seasonal, temporal, and spatial variations in the incidence of Burkitt's lymphoma have long been linked to the prevalence of malaria,[31,55,56] and in 2008, direct evidence of a link between malaria, EBV, and endemic Burkitt's lymphoma emerged [57,58]. Two epidemic- logical studies showed that the risk of Burkitt's lymphoma was greatest in people with the highest titres of antibodies against both EBV and Plasmodium falciparum [19, 59].

Severalstudieshaveshownthatmalariacancausea profound dysregulation of EBV persistence and immunity in children [60–65]. These results suggest that malaria increases the risk of endemic Burkitt's lymphoma through interactions with EBV-infected Bcells.Forexample,thecysteine-richinterdomain1αofthe P falciparumerythrocytemembraneproteininduces reactivation of EBV.66 Additionally, P falciparum has a ligand for toll-like receptor 9 [67]. Signalling through toll- like receptor 9 was shown to induce the enzyme activation-induced cytidine deaminase in human B cells [68, 69]. Overexpression of this enzyme induces the immunoglobulin-MYC translocations [70].Characteristic of Burkitt's lymphoma. Normal B cells undergo apoptosis if MYC is overexpressed after an activation-induced cytidine deaminase-mediated translocation. However, EBV latent proteins are ant apoptotic, which might allow the B cells to tolerate the translocation and ultimately give rise to a malignant clone. In malaria-endemic regions, diminished EBV-specific cytotoxic T-cell responses were observed in children at peak age of Burkitt's lymphoma incidence [61]. Children with acute malaria also have transient loss of EBV-specific T-cell control [71]. Malaria probably increases the risk of endemic Burkitt's lymphoma by increasing the number of latently infected B cells through viral reactivation and reseeding of the latent pool; by causing loss of immune control of latently infected B cells; and by inducing MYC trans- location through a mechanism mediated by activation- induced cytidine deaminase.

HIV Infection

Burkitt's lymphoma occurs in HIV-infected patients with high CD4 T-cell numbers, which suggests that immunosuppression is not in itself the cause of the malignancy. Chronic antigenic stimulation of B cells, as in sustained P falciparum infection or chronic HIV infection, might be a common pathogenetic mechanism of endemic and HIV-associated Burkitt's lymphoma. HIV-infected patients with Burkitt's lymphoma have high serum

concentrations of soluble CD30 and CD23— markers of B-cell activation—before emergence of lymphoma [72–74]. Patients with chronic HIV viraemia, even if on antiretroviral therapy, have a higher risk of developing HIV-associated lymphomas than those with unmeasureable viral loads [75, 76]. The virus might affect B cells through dysregulation of activation-induced cytidine deaminase and chronic B-cell activation. The enzyme has been detected in peripheral lymphocytes in HIV-infected patients with lymphoma, but not in HIV- positive patients without the malignancy, nor in healthy controls [77]. Impaired immune surveillance and deregulated cytokine release could promote survival of B cells with chromosomal rearrangements induced by overexpression of the activation-induced cytidine deaminase.

The effect of HIV infection on the risk of endemic Burkitt's lymphoma is unclear. Different clinical presentations and tumour behaviour have been noted between HIV-infected and uninfected people [78, 79]. An association was first reported from a Ugandan study,24 but neither work in Côte d'Ivoire [80] nor in Zambia [81] confirmed this link. Preliminary data from Malawi identified an increased risk of endemic Burkitt's lymphoma in HIV-infected patients, 58 but updated analyses found no significant association [82].

Other Possible Cofactors

Arboviruses and schistosome parasites have both been suggested as causative cofactors of endemic Burkitt's lymphoma, although evidence is sparse [30]. The plants Euphorbiae tirucalli and Jatropha curcas are common in areas where the endemic type of the disease occurs. The milky sap of these plants contains dipterene esters that can activate latent EBV and induce rearrangements of chromosomes in about 10% of exposed EBV-infected B cells [83–85].

Clinical Presentation

The most common site of presentation in sporadic Burkitt's lymphoma is the abdomen (60–80%) [21]. Presenting symptoms include abdominal pain (25% of patients have ileocaecal disease—either a right lower quadrant mass or pain from intussusception), distension, nausea and vomiting, and gastrointestinal bleeding [86, 87]. The next most common site is the head and neck, including lymphadenopathy and involvement of the nasal or oropharynx, tonsils, or sinuses. The jaw is infrequently implicated. Bone marrow is infiltrated in roughly 20% of patients. Some cases are classified as Burkitt's leukaemia and are characterised by extensive

marrow infiltration (more than 25% blasts), with possible bone pain as a presenting feature. Rare presenting sites include the mediastinum, CNS, skin, testes, breasts, and thyroid gland.
Patients with endemic Burkitt's lymphoma most frequently present with jaw or per orbitalswellings, or abdominal involvement (of retroperitoneal tissue, gut, ovary, or kidney) [88]. 15% present with sudden paraplegia and incontinence. Infiltration of bone marrow is rare. Jaw involvement is common in young children (peak ages of incidence 3–7 years) [89]. In low- income countries, such as in sub-Saharan Africa, many children present with advanced disease. In a study of 84 Malawian children with Burkitt's lymphoma, [26] (31%) presented with facial disease only and [52] (62%) with abdominal disease; [58] (69%) had St Jude stage III or IV disease.88 Patients are commonly malnourished at diagnosis [90].

Histopathology and Immunocytochemistry

Burkitt's lymphoma is a highly aggressive B-cell non- Hodgkin lymphoma characterised by monomorphic medium-sized cells with a very high proliferation rate. The cells are intermediate in size and contain coarse chromatin and prominent basophilic nucleoli. Some plasmacytoid and atypical variants show more nuclear pleiomorphism. In tissue sections, typically the cells seem to be moulded and the cytoplasm is deeply basophilic with squared-off cytoplasmic margins. The proliferation index is almost 100%, with a high turnover shown by increased apoptosis. A "starry sky" appearance is due to scattered tingible-body-laden macrophages that contain apoptotic tumour cells [43]. The cells are always of B-cell lineage (CD20 positive and CD79a positive). CD10 and Bcl-6 are commonly co expressed, but the cells are generally negative for Bcl-2. There is a scarcity of T cells in the background.91 Epstein-Barr-encoded RNA can be identified by fluorescence in-situ hybridisation. Classification is difficult when the cells have the morphology of diffuse large B-cell lymphoma but the genetic and immunophenotype features of Burkitt's lymphoma. Some of these cases are now classified as "B-cell lymphoma, unclassifiable, with features between diffuse large B-cell lymphoma and BL [Burkitt's lymphoma]" [92]. However, distinct molecular changes in Burkitt's lymphoma could provide a more reliable diagnosis.

Diagnosis

High-Income Countries

Diagnosis of Burkitt's lymphoma should be confirmed by microscopy and immunocytological analysis. The recommended approach is to remove and examine the most accessible disease-containing tissue. This sample could be a superficial lymph node or

malignant pleural fluid. Excision biopsy of a lymph node is preferable to fine-needle aspiration, which does not provide sufficient tissue for all the investigations required. In some cases a laparotomy or laparoscopy is necessary to obtain tissue.

Several essential investigations should be done in patients with suspected Burkitt's lymphoma: full blood count, differential and film, ESR and urea and electrolyte measurements, liver function tests, a clotting screen (pro- thrombin time, partial thromboplastin time, D-dimers) to assess renal and hepatic involvement or dysfunction, serum lactate dehydrogenase and urate measurements (to assess tumour turnover), EBV status, and chest radio- graphy. The radiograph should be done before any anaesthetic is given, to look for mediastinal lymph nodes with or without pleural effusions. CTs of chest and abdomen show disease extent and can be done after tissue diagnosis unless airway obstruction is suspected. PET scanning is recommended, but is not essential. After confirmation of the diagnosis, bilateral bone-marrow aspirates, trephine cores, and cerebrospinal fluid should be examined for the presence of malignant cells [93].

Low-Income Countries

Diagnostic facilities in low-income countries are likely to be restricted. The most common diagnostic test is cytological examination of a fine-needle aspirate. Results are commonly not available at the time of clinical decision making. Ultrasonography is useful to detect intraabdominal masses. Examination of cerebrospinal fluid and bone- marrow aspirates will detect CNS and bone-marrow involvement. If possible radiography should be done, as well as basic blood tests (such as full blood count, urea and electrolyte measurements, and liver function tests).

Common co infections (e.g., malaria, helminth infections) should be identified and treated before chemotherapy begins. HIV infection should be noted so that antiretroviral therapy can be given after chemotherapy for Burkitt's lymphoma. Tuberculosis and Kaposi's sarcoma should be ruled out either clinically or histologically.

Prognostic Markers

Therapy is guided partly by clinical and histopathological staging with biological features beginning to inform therapeutic strategies. Clinically, prognosis is determined by staging, which includes extent of disease [94]. The St Jude/Murphy classification for Burkitt's

lymphoma is the most common staging system used (panel) [95]. Cytogenetic analysis is important in diagnosis to identify MYC deregulation and the presence of additional cytogenetic abnormalities, some of which have been shown to have prognostic significance.PET is helpful to assess residual or recurrent disease. Burkitt's lymphoma produces a very strong signal with fluorodeoxyglucose- PET. Disease can be monitored regularly throughout treatment. Because of the high fluorodeoxyglucose avidity of the lymphoma, a single scan can provide valuable confirmation of recurrent disease [96].

The role of minimal residual disease monitoring in Burkitt's lymphoma is not yet established. Some clinicians routinely monitor for it, although findings are not generally used to guide treatment. The presence of mini- mal residual disease in bone marrow (which is also a measure of minimal disseminated disease) is better applied to the prediction of high risk of treatment failure. The construction of primers for use in monitoring of minimal residual disease is generally based on the original tumour material: 5VH and 7DH family primers in com-bination with one JH consensus primer for immuno- globulin heavy chain rearrangements; [97]. BIOMED 1 primer set for kappa light chain deletions; and BIOMED 2 primer set for immunoglobulin kappa v–J [98]. Other strategies have been used such as patient-specific long-range PCR with primers related to the (8:14) translocation and primer pools from the immunoglobulin V [99]. However, the H1–H7 most accurate analysis uses primers determined by the original tumour material. Assessment of prognosis by retrospective molecular profiling (e.g., array-based com- parative genomic hybridisation and gene-expression profiling) does not seem to offer any advantages over standard morphology and immunocytochemistry [100]. In low-income countries, disease staging and response to treatment (including ultrasonography of the abdomen) might be the only prognostic guides available.

Management

High-Income Countries

Treatment of Burkitt's lymphoma in most centres is guided by the FAB LMB study (cooperative study between the Children's Cancer Group, the Societieś Française d'Oncologie Pédiatrique, and the UK Children's Cancer Study Group) [86,87] or Berlin–Frankfurt–Münster protocols. The former con- sists of initial cytoreduction with cyclophosphamide, prednisolone, and vincristine, followed by more intensive chemotherapy in varying combinations. The risk of pronounced tumour lysis is high in the first few days of

therapy, but the use of urate oxidase has reduced this danger substantially. Because of the toxic effects of these protocols, sophisticated supportive care is needed, which is not possible for most low-income countries.

Management of Burkitt's lymphoma can be divided into three broad groups of patients. Children with localised disease that has been completely removed surgically need only two cycles of moderately intensive chemotherapy such as cyclophosphamide, vincristine, prednisolone, and doxorubicin. Children with residual or stage III disease need at least four cycles of dose-intensive chemotherapy, such as two cycles of cyclophosphamide, vincristine, prednisolone, doxorubicin, and high-dose methotrexate, followed by two cycles of cytarabine and high-dose methotrexate with concurrent intrathecal treatment. Children with CNS or bone-marrow involvement are given similar treatment to the second group, but receive up to eight courses of dose-intensive treatment. This therapy typically involves two courses of cyclophosphamide, vincristine, prednisolone, doxorubicin, and high-dose methotrexate followed by two courses of high and low doses of cytarabine, and etoposide) and four courses of maintenance with varying combinations of vincristine, prednisolone, high-dose methotrexate, cyclophosphamide, doxorubicin, cytarabine, and etoposide. Intrathecal therapy is given alongside systemic chemotherapy.

The use of rituximab (anti-CD20) in primary therapy has been assessed, and some small single-centre studies report encouraging results. [101]. Data are awaited from a Children's Oncology Group pilot study on toxic effects (ANHL01P1) in which rituximab was given to patients with stage III and IV Burkitt's lymphoma. The next UK trial will randomise the use of rituximab for stage III and IV patients.

Low-Income Countries

Therapy needs to be modified in accordance with local conditions to avoid unacceptable treatment-related mortality. The intensity of treatment is determined by the amount of available supportive care, a child's tolerance of chemotherapy, and the extent of comorbidities. In Malawi, for example, the treatment for Burkitt's lymphoma of all stages is intravenous cyclophosphamide (40 mg/kg on day 1 and oral cyclophosphamide 60 mg/kg on days 8, 18, and 28). Intrathecal hydrocortisone (12·5 mg) and methotrexate (12·5 mg) are given with each treatment cycle. The cost of this 28-day treatment is less than US$50.88

Previous attempts to use intensive treatments with high-dose methotrexate resulted in unacceptably high treatment-related mortality (11 of 42 participants) [102].

In a French-African Paediatric Oncology Group study, two moderately intensive modified LMB 89 protocols (including high-dose methotrexate and cytarabine) were used in several French-speaking African countries.114 Of 306 patients, 71 (23·2%) died during treatments; 40 (13·1%) deaths were attributed to infection [103].Adequate and timely supportive care, even if not as intensive as in high-income countries, is essential, and should include measures to prevent and manage tumour lysis syndrome, nutritional support (malnutrition is associated with chemotherapy-related neutropenia90), antiemetics, transfusion support, and a local fever protocol. In low-income countries, many patients do not complete the full course of treatment [104-109]. Travel distances and expense, treatment costs, and poor knowledge of the disease all contribute to non-completion [110-113]. Ideally, medical treatment would be free to the patient and appropriate social support would be provided to enable treatment to be completed.

Conclusion

In low-income countries better diagnostic testing is needed. When only morphology is available, tumours are probably incorrectly classified as Burkitt's lymphoma.Additionally,ahighstandardofsupportive care and medical infrastructure is necessary to deliver the most effective therapy. New, effective, and inexpensive therapies are needed for low-income countries. One possibility is to use compounds with histone deacetylase inhibitor activity as adjuvant therapy.These agents stimulate tumour cells to differentiate and undergo apoptosis, and also induce virus lytic replication in EBV-positive tumours. Tumours with some viral replication have been shown to be more sensitive to chemotherapy than those without any replication.For example, sodium phenylbutyrate induces EBV lytic replication in susceptible B-lymphocyte cultures.

With improved molecular profiling and understanding of the cause of Burkitt's lymphoma, targeted therapy will be developed that still has excellent cure rates but has reduced toxic effects. Potential targets could include the MYC oncogene, DNA methyltransferase inhibitors, cyclin-dependent kinase inhibitors, and proteosome inhibitors. As further biological factors are identified, more targeted therapies will probably be developed.

In the 1980s Guy de Thé described Burkitt's lymphoma as "the Rosetta stone of cancer". This description remains true now. In attempting to understand Burkitt's lymphoma, much is still to be learnt about how all cancers develop, grow, and are treated.

Carcinogenesisin Squamous Cell Carcinoma of Head and Neck (SCCHN) by Evasion of Apoptosis- A Review of Literature

Hemani.K[1],Dhanalakshmi Ravikumar[2],
Graduate Student[1],Senior Lecturer[2],Department of Pedodontics and Preventive Dentistry,
Saveetha Dental College,Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, Iindia

Abstract

Apoptosis or a programmed cell death, is a physiological orchestration of molecular mechanism that is triggered by a noxious stimuli that has resulted in cellular and DNA damage. It is a mechanism to retain the integrity of the genome. It is regulated by proapoptotic and antiapoptotic molecules. Evasion of apoptosis ,one of the hallmarks of cancer results in abnormal growth of a mutated cell. The most intensely studied gene involved in carcinogenesis is a tumour suppressor gene TP53. Mutation in the TP53 gene can result in dysregulation of apoptosis which leads to genomic instability and thereby carcinogenesis.

This review aims to highlight the role of apoptosis in normal health ,and the molecular mechanisms of carcinogenesis by evasion of apoptosis , of Squamous cell carcinoma of head and neck (SCCHN).

To analyse the various cellular and molecular mechanismsthat interfere with the normal function of tumour suppressor gene- TP53 causing dysregulation and DNA mutation mediated evasion of apoptosis, a hallmark of cancer.

This review, will focus on Apoptosis and carcinogenesis of squamous cell carcinoma of the head and neck (SCCHN) by evasion of apoptosis . By determining these molecular pathways, basis for modulation in gene therapy for advanced and refractory SCCHN can be established

KeyWords: *Apoptosis, Squamous cell carcinoma of head and neck ,SCCHN, p53, TP53*

Introduction

Head and neck squamous cell carcinoma (HNSCC) a malignancy that presents in the head and neck region commonly involves the oral cavity, pharynx and larynx. It is by far the commonest subtype of cancer, and is the sixth most common site(1). The main risk factorsattributed are smoking , alcohol , and tobacco or a combination . Infection with the human papilloma virus (HPV) has emerged as a major risk factor, The associated complex genetic mutations complicates the management , rendering very low survival rates. The many molecular mechanisms caused by genetic and epigenetic factors, associated with malignancy have been reviewed by Park(2) and updated thereafter as hallmarks of cancer, involved in HNSCC .

In 2000, Hanahan and Weinberg (3)described six characteristics, necessary for a malignanttumour to develop as hallmarks of cancer,. These are (a) acquisition of sustained proliferative signalling (b) evasion of growth suppressor signals (c) resistance to cell death (evasion of apoptosis)(d) replicative immortality (immortalisation) (e) induction of angiogenesis and (f) activation of tissue invasion and metastasis. A later update in 2011 (4) added two emerging hallmarks(g) deregulation of cellular energy metabolism, and (h) evasion of immune destruction.The last two were classified as emerging hallmarks, as they may or may not prevail in all cancers.Twoenabling characteristics, genome instability and mutation,and tumour-promoting inflammation were then defined which could predispose to carcinogenesis.This review, will focus on Apoptosis and carcinogenesis of squamous cell carcinoma of the head and neck (SCCHN) by evasion of apoptosis.

Apoptosis

Apoptosis is a programmed cell death mechanism carried out by the cell’s own metabolism to establish development and homeostasis in metazoans(5,6). A cell that is subjected to a DNA damage,hypoxia or any other cellular abnormalities, activates this process through various pathways to retain its genetic stability(7). There is a perenial threat posed to the genetic stability in the form of and external and internal environmental pollutants ,irritants, like pollution ,food,chronic trauma ,stress, that act as cytotoxins, which trigger a sequence of reactions towards genotoxicity affecting a host of cells every day of life. In the attempt to challenge the insults, the body's innate defence mechanisms operates by initating a sequence of reactions for repair, but persistance of abberent stimuli results insenescence, or apoptosis to maintain integrity of the genome. The repair when it fails,orifabberant, results in genetic

mutations, and further cell proliferations with the mutant gene, needs to be arrested or expelled.

Ireversible cell cycle arrest or cellular senescence, of mutant cells acts as a protective barrier against any further proliferation of mutant cells, and is therefore a potent tumour suppressant providing a defence against malignant transformation of pre malignant leisons(8,9,10)

Elimination is performed by two major mechanisms necrosis and, apoptosis,Autophagy,lysosomal cell death, mitotic catastrophy(11,12) are the more recent discoveries in the mode of cell death . Necrosis involves plasmatic rupture and cell death associated with inflammation(13). Apoptosis happens by fragmentation of DNA that is phagocytosed by macrophages with no associated inflammation(14). Induction of apoptosos is either by promotion of proapoptoticfactors ,orsupression of anti proapoptotic factors in tumour cells or by infection of viral particles targeting specific transformed cells(15)

Default orretardation or delay in the initiation of apoptosis, retains the mutant gene in the body , and proliferation of such cells results ina tumour. The stimulus that initiated it is considered as a potent carcinogen.Preserving and conserving normal genetic material is therefore necessary forexistance and normal reproduction of life in this planet.

Defects in apoptosis may cause cancer or autoimmunity and enhanced apoptosis may lead to degenerative diseases(16), immunodeficiencies and infertility. Cancer cells inhibit apoptosis mainly by ignoring signals from extrinsic pathway and resetting the balance of intercellular pro and anti apoptotic molecules. This implies that apoptotic signals help in maintaining genomic integrity ,but dysregulation of apoptotic mechanism may lead to cancer development and also makes the cells resistant to cancer treatment (17). This evidently proves that evasion of apoptosis is a prominent hallmark of cancer (18).

Apoptosisor programmed cell death is initiated by three major mechanisms . An intrinsic mechanism which is receptor triggeredandinitated by ligation to death receptors inducing caspase-8 activation.Thesecond,an intrinsicormitochondrial pathway , that is triggered by cellular stress leading to activation of Caspase -9. The third is the granzyme B pathway where the cytotoxic cell proteases granzyme B is delivered to target cells . On a molecular basis all mechanisnms lead to caspase activation and DNA fragmentation by proteolytic activation of Caspase 3 , 7 from their inactive zymogens. Mitochondria plays an important role by releasing proapoptotic proteins into the cytosol in response to diverse stimuli which is regulated by proteins of Bcl-2 family (18)

TP53, a critical DDR(DNA damage response) gene is a known tumor suppressor gene, that encodes the p53 protein. p53 is considered to play a critical role in programming apoptosis to prevent cancer (19, 20). In 50% of cancers p53 is inactivated by mutations(21).Studies reveal that itmediates both cell autonomous and non cell autonomous DDRtoalleviate progress of cancer This review aims to explain the apoptotic pathways and how evasion of apoptosis promotes carcinogenesis in SCCHN.

Apoptotic Pathways

Extrinsic pathway-

Tumor Necrosis Factor (TNF) family receptors contain two major death domains (DD) containing receptors that use caspase activating signaling mechanisms , they are Fas (fibroblast associated antigen also known as Apo-1/CD95) and tumor necrosis factor receptor (TNF-R).Others includeDR3/Wsl-1/Tramp, DR4/TRAIL-R1, DR5/TRAIL-R2/TRICK2/Killer and DR6(22). When the death receptors are ligated it induces the formation of Death Inducing Signaling Complex (DISC), where the adaptor FADD/ TRADD binds to the death domain and induces the pathways that activate caspase 8 and 10. The activated caspase 8 cleaves procaspase 3 and leads to apoptosis. It also cleaves BH 3, the only proapoptotic protein that contains Bid and forms truncated Bid(tBid) which induces cytochrome c release from mitochondria to activate caspase 9 and 3 to start apoptosis(18) .

Intrinsic Pathway

Intrinsic pathway or mitochondrial pathway involves Bcl-2 family members. It contains anti apoptotic members(Bcl-2, Bcl XL) and pro apoptotic members (Bax, Bak). BH3 is the only protein that is pro apoptotic , it contains Bim and Bid to help in the actions of Bak/ Bax. When extra or intra cellular stresses activate the pathway, Bak/ Bax act on mitochondria through BH3 proteins and cause release of cytochrome into cytoskeleton. By homo oligomerisation of Bim and Bid , cytochrome c activates Apaf-1 to activate pro caspase 9 which in turn activates caspase 3,6,9 and causes apoptosis (23). Smac and Omi proteins neutralise the inhibitory effect of IAPs (inhibitor of apoptosis proteins)(24,25).

This pathway also includes the action of cytotoxic T cells and Natural killer cells (NK cells). They activate granzyme B (Gra B) which cleaves several caspase and leads to the activation of endonuclease and catabolism of cytoskeleton and it is followed by apoptosis.(26).

TP53-Tumor Suppressor Gene

TP53 is an important cell cycle regulator that plays a central role in the regulation of the cell cycle arrest at G1 phase and promotes cell death by activating apoptosis by various parallel pathways (27) that may or may not depend on transcriptional events to prevent damaged DNA from being passed on to daughter cells. Tumor cells inhibit apoptosis by dysregulating a key component that is important for upstream and downstream regulation of p53 mechanism for apoptosis. Wild type p53 tumours inactivate positive regulators of p53 such as p14ARF (28) or over activation of negative regulators of p53 activity such as Akt (29).

p53 Pathway for Apoptosis

The p53 gene was localized to chromosome 17p13 spanning 20 kb, consisting of 11 exons and encoding a 2.9-kb mRNA. The p53 protein contains 393 amino acids, is localized to the nucleus, and is expressed in all cells. Most mutations in the p53 gene are missense mutations occurring in the highly conserved central domain of the protein .p53 which is known as the 'guardian of the genome' follows a specific pathway to bind to DNA but tumor derived mutants lack this mechanism, thus disabling this mechanism causes tumorigenesis (30) . p53 senses a stress and activates the pathways through its transactivational capabilities. When a stress is felt, proteins like Ataxia Telangiectasia Mutated (ATM) and Chk2 phosphorylates p53 (31) . Similarly the oncogenes in mitochondria also activate p53 through p19ARF by inhibiting the action of Mdm2 mediated ubiquitination of p53 (32). p53 binds to Mdm2 gene and stimulates transcription of this gene into messenger RNA (mRNA) to translate it into protein (19). The level of p53 rise when Mdm2 binds to p53 and reduces transcription of Mdm2 gene and closes the feedback loop. The activated p53 then activates proapoptotic members (Bak/Bax) and suppresses the antiapoptotic members(Bcl-2,Bcl- XL) of Bcl2 family. The BH3 contains activates (Bim,tBid) that induce mitochondrial outer membrane permeability and sensitisers or derepressors (Bad,Bmf,Noxa,Puma) that neutralises antiapoptotic proteins . These proteins bind with Bax/Bak to act on mitochondria to start apoptosis (26).

As expression of both Bcl-2 and Bax is regulated by p53tumor suppressor gene(33),human B cell lymphoma has over expression of Bcl-2 (34) which proves failure of cell death which contributes to cancer. In mitochondria it transactivates the apoptotic effector mechanism and

induces Apaf-1 which is a co activator of caspase 9 and starts the caspase cascade. p53 being an up regulator of caspase 6, it creates chemo sensitivity (35) in cells and starts apoptosis.
Previous studies in cell lines,(36) revealed that introduction of p53 intohead and neck cancer cell lines induced growtharrest and apoptosis.Crowe(37) demonstrated that head andneck SCC lines express bcl2, bak, and bid but notbax and bad.(38)p53 inhibited bcl2 expression by twofold tothreefold in both SCC25 and SCC9 stable clones.p53 expression had no effect on bak and bid levels, nor did bax affect expression of any bcl2-related proteinA study(37) using wild-type cell linesp53 expression to three head and neck squamouscell carcinoma (SCC) lines containing well-characterizedmutations in this gene.(39) demonstrated that p53 did not induce growth arrest or celldeath in these lines but increased levels of DNAdamage–induced apoptosis that was dependenton bcl2 but not baxexpressionWild-type p53 wastranscriptionally active and inhibited cellularproliferation by slowing the G1 to S phase transition.suggestingthat p53 expression decreased the number of cellsentering S phase from G1.

In extrinsic pathway it sensitises death receptor ligand Fas/TNFR and induces apoptosis directly or enhanced cell death. Bid may facilitate crosstalk between extrinsic and intrinsic pathway (40).
p53 also transactivates other genes like PERP , p53AIP1 and genes that increase reactive oxygen species (ROS) (41).p53 can transactivate genes that short circuit antiapoptotic pathways, this is prominent in its ability to regulate PTEN, thus changes in PTEN can compromise p53 mediated apoptosis in some cell types (42). TP53 can produce changes in REDOX metabolism and increase the number of reactive oxygen species (ROS) and antioxidants which suppress p53 mediated cell death (30).
Carcinogenesisis induced by failure of the above mentioned pathways and other machanisms that are beyond the scope of this review article.Many molecular mechanisms are adopted bytumorcells to suppress apoptosis. Tumor cells can acquireresistance to apoptosis by the expression of antiapoptoticproteins such as Bcl-2 or by the downregulation or mutationofproapoptotic proteins such as BAX. Since the expressionof both Bcl-2 and BAX is regulated by the p53 tumorsuppressorgene(27)

Mechanisms of the Hallmarksof Cancer

Acquisition of sustained proliferative signalling - EGFR (epidermal growth factor receptor) is a key growth factor receptor involved in manycellular pathways that regulate growth and cell survival.EGFR is overexpressed in up to 90 % of HNSCC(43), andhigh expression of EGFR is associated with poor clinicalprognosis(44). Transforming growth factor-a (TGF-a), anEGFR ligand, is also overexpressed in cases of HNSCC,resulting in autocrine signalling (43). Radiation increases theexpression of EGFR in cancer cells, and blockade of EGFRsignalling sensitizes cells to the effects of radiation.

In addition to genetic mutations alterations in genetic control mechanisms by epigenetics should also be considered .The epigenetic processes include DNA methylation, histone acetylation, phosphorylation, ubiquitylation, and sumoylation. Such epigenetic changes can facilitate hallmark acquisition through altering the activity of normal genes.

The role of increased gene promoter methylation in HNSCC has been reported for several genes including CDKN2A, RARß2 and CDH1 (45). Silencing of RARß2 by promoter hypermethylation is an early event in head and neck carcinogenesis(46).

Hypermethylationcan also silence micro RNAs (miRNAs) with tumour suppressor functions,as a decrease in the levels of hsa-miR-205 and hsa-let-7d expression is a strong indicator of poor survival in patients with HNSCC (47). Target of hsa-let-7d is KRAS, which is asmallGTPase downstream of many growth factor receptors, whose overexpression could lead to sustained proliferativesignalling. KRAS gene is overexpressed in45 % of HNSCC (48).

Evasion of growth suppressor signals - The most important tumour suppressor protein is p53.p53 associates with the E3 ubiquitin ligaseMDM2, which targets p53 for proteolytic degradation, allowing it to accumulate in the cell.The TP53 gene is mutated in about 60 % of allHNSCC resulting in loss of tumour suppressor function(49). In the remaining 40 % of tumours, TP53 function isinhibited by an interaction with certain proteins.The E6oncoprotein produced by HPV-16 binds p53 and targets itfor degradation in about 20 % of HNSCC(50). HPV is amajor risk factor for squamous cell carcinoma of theoropharynx.

Retinoblastoma protein (Rb) is another major tumoursuppressor protein.Rb suppresses progression through the cell cycle by binding toand inhibiting the E2F transcription factor(51).The HPV oncoprotein E7 also affects thispathway by binding Rb and targeting it for degradation.Tp53 is not mutated in HPV-associated HNSCC expressingE7

Resistance to cell death - p53 is a key proteininvolved in the onset of apoptosis (36). It can cause thetranscription of the pro-apoptotic proteins Noxa, Puma andAip1 and repress the transcription of the anti-apoptoticBcl-2 protein.EGFR signalling affects not only sustained proliferationbut also evasion of apoptosis through its downstreameffector STAT3. STAT3 is a transcription factor with manyroles, including suppression of apoptosis. An increase inEGFRsignalling thereforecan inhibit apoptosis(52,53).

Phosphoinositide 3-kinase (PI3K), another downstreameffector of EGFR, is also commonly overexpressed inHNSCC. Presence of PIP3 in the plasma membrane results inrecruitment of PDK1 which recruits AKT(54). AKTphosphorylates many target proteins to promote cell survival. PI3K is overexpressed in 37 % of HNSCC.

Replicative immortality - In humans, telomerase is active inthe embryo but is lost later in life. Many cancersreactivate telomerase and so become immortal. This is thecase in HNSCC, where telomerase activation is seen in78 % of cancers, 85 % of precancerous tissue, and 53 % ofadjacent normal tissue (55).

Induction of angiogenesis- As the tumour increases in size , the prevailing hypoxia induces angiogenesis. Hypoxia causes increased production of proangiogenic factors, such as vascular endothelial growthfactor (VEGF), platelet-derived growth factor (PDGF),fibroblast growth factors (FGF 1 and 2) and interleukin(IL-8). andsupression of anti-angiogenicfactors such as interferons(56). VEGF is a pro-angiogenicfactor that binds receptors on endothelial cells, triggeringtheir proliferation and migration to facilitate angiogenesis.High VEGF expression has been documented in HNSCC(57). Expression of VEGF or its receptors is increased in50 % of premalignant and 75 % of malignant oral andlaryngeallesions(58)

Tissue Invasion and Metastasis

The tumour undergoes dysmorphic changes and invades the adjacent tissues, undergo epithelial to mesenchymal transition. E-cadherin and the cateninsa and b form a key protein complex at adherens junctions which link neighbouring cells. E-cadherin and the catenins are downregulated in 59% and 72 % respectivelyof HNSCC, and the downregulation is associated with lymphnode metastases(59).

SPARC is a glycoprotein associated with the ECM. It can increase cell permeability bycausing the production of enzymes which break down themembrane(60). This can facilitate tumour extravasationwhere cells migrate from the blood stream through

thevascularendothelium and into the tissue(61). In this way,SPARC overexpression may facilitate metastasis. SPARC/osteonectinare genetic markers for SCCHN

Reprogramming energy metabolism

Abnormality in tissue metabolism is an emerging hallmark of cancer. Alteration in oxygen consumption and altered aerobic glycolysis have in recent time been identified using nuclear magnetic resonance studies (62). Increased levels of lactate (awaste product of glycolysis) and monocarboxylate transporters (proteins for lactate export) were found in HNSCC cells.

Evading immune destruction - The immune response to HNSCC is also impaired by theapoptosis of CD8, lymphocytes at the tumour site, andreactive lymphocytes are also depleted in the circulation(63).

Enabling Characteristics

Genomic instability- TP53 mutations can increase genomic instability.An important function of p53 is in the DNA damageresponse, which is activated by the presence of damage andarrests the cell cycle to allow time for repair. If this processis disrupted, more mutations can be tolerated. A TP53mutation could also facilitate immortalization.(52)

The importance of functional p53 as a barrier to cancer is reflected in the progression to HNSCC, mutant TP53 was found in 29 % of hyperplastic lesions,46 % of dysplastic lesions, and 58 % of HNSCC(40,41).Thepresence of a TP53 mutation in a premalignant lesion is a very strong indicator of progression to carcinoma and has apositive predictive value of 86 % (64).

Tumour-Promoting Inflammation

Tumours normally invaded by a high density of immune cells including granulocytes, monocyte-macrophages, mast cells, dendritic cells, lymphocytes and fibroblasts, by chemokines(65,66). These immune cells enhance progression of tumour development with factors that facilitate acquisition of the hallmarks of cancer, such as growth factors and angiogenic factors.

Inflammatory cells also release reactiveoxygen species, which are highly mutagenic and canincrease genomic instability (67). COX-2, an enzymeinvolved in the production of inflammatory prostaglandins,and maintenance of blood flow, is overexpressed in 71 %of HNSCC, where it is associated with VEGF productionand perhaps with more aggressive

disease with lymph nodeinvolvement(68). Chronic infection in the oral cavity(periodontitis) is associated with more aggressive oralcancer, and bad dental hygiene may contribute to theassociation of cigarette smoking with HNSCC (69).HNSCC has a role in inflammation, because it expressesToll-like receptors (TLRs), which are a part of the ancient innate immune system. TLRs are usually expressed oninflammatory cells guarding sites such as mucosal membranes, where they trigger local inflammation in responseto binding particular molecules from pathogens such aslipopolysaccharide and double-strand RNA. TLRs onHNSCC probably enhance inflammation triggered bybacteria associated with the tumour. This may have someprotective function but at the same time can promotetumour progression by mechanisms such as induction ofproliferation, activation of NF-jB and resistance to naturalkiller lymphocytes (70).

Effect of Therapeutic Drugs on p53

An extensive and thorough understanding of the various molecular mechanisms have contributed largely towards therapeutics for cancer. Therapeutic drugs aim either at inducing proapoptotic proteins or in inhibiting the over expression of antiapoptotic proteins. Thus in case of a mutated p53, the pharmacokinetics involved , is aim at reviving apoptotic pathways in addition to other modes.

Action of 5 Fluorouracil(5 FU)

Fluoropyrimidine 5 Fluorouracil (5 FU) is acommonly used anti cancer drug but its resistance remains a problem. FU targets the tumor suppressor and triggers the cell cycle(26).5FU induced apoptosis is p53 dependent . Apoptosis can occur in p53 mutant cell lines by a mechanism still unknown(71,72).

Action of Doxorubicin on p53

Action of doxorubicin is more active against p53 wild type tumor xenografts than p53 mutant and null cells(73). Doxorubicin induces apoptosis that is dependent on the presence of wild type p53 (74).Negative clinical outcomes due to failure of the drugs to induce apoptosis in some tumor cases are also reported (75).

Action of Herbs

Anticarcinogenic and antioxidant effect of herbs are under study recently. Apoptotic potential of B. monnieri.against oral cancer has been evaluated (76) , but further studies are required to confirm on the role in apoptosis

Conclusion

The updated mechanisms that explains the hallmarks of cancer are a useful platform to understand the underlying molecular and cellular processes involved in the development of HNSCC. There may be more than one mechanism acting in each hallmark process. Some established molecular mechanisms such as mutation of TP53 and overactivity of EGFR are so frequent in HNSCC as to appear almost inevitable in carcinogenesis. The study of these innumerable and complex mutations could lead to better prognostic markers and the personalisation of therapy according to the characteristics of the particular tumour. The hope is that molecular-targeted therapies will play an increasingly successful role in the management of head and neck cancer

Abstract

Epinephrine is widely used as an additive in local anaesthetics (typically in concentrations of 1:100,000) to improve the depth and duration of the anaesthesia, as well as to reduce bleeding in the operative field. Epinephrine counteracts the anaesthetic'slocalized vasodilator effects in subcutaneous and sub mucosal vessels, thereby reducing the risk of anesthetic toxicity by decreasing the rate of systemic absorption from the site of injection. Epinephrine is also impregnated in cotton cord that is inserted into the sulcus between a tooth and the surrounding gingiva, as a gingival retraction cord improving access for tooth preparation and allowing dental impression material to more readily flow into the sulcus to record details of teeth prepared for crowns. The epinephrine likewise tightens the blood supply to contiguous tissue, in this manner allowing the impression to be secured without Contamination by bleeding. Hypertension affects nearly 50 million people in the United States and underlies most cardio- vascular disease, its diagnosis and control should be of concern to all health care providers. Many people have undetected hypertension, and current levels of detection and control need to be improved. Clinical Implications.All health care providers, including dentists and members of the dental team, need to be involved in detection and management of this important public health problem. The dentist can play an important role in the detection and management of hypertension.

Key words: *epinephrine, hypertensive patient, cardiovascular disease, extraction, hemodynamic changes.*

Introduction

Epinephrine is commonly used in health care applications as life savers. Such as in management of anaphylaxis and cardiac arrest. The drug is produced in human body from adrenal gland above the kidney. Though it is produced in our system their requirements in emergency procedures are high, and always there is a confusion regarding dose limits for epinephrine. Especially when it is administered in patients with cardiovascular diseases.Epinephrine was first added to the local anaesthesia ester procaine over 100 years ago, which is not in current practices. It is one of the widely used vasoconstrictors in dentistry. However, the use of local anaesthetics containing epinephrine in cardiac compromised patient during dental procedures has been controversial. Epinephrine has been argued as a potential risk factor that can cause cardiovascular complications. Hence many studies have been conducted to evaluate the safety of epinephrine in dental treatment.

There are numerous physiological effects of epinephrine, as it is reason for the reaction “flight or fight” in all mammals. Some variations in this response depends on the predominant type of adregenic receptors in the target organ.[1]Epinephrine increases the heart rate and the force of ventricular contraction, which eventually increases cardiac output. This increasedcardiac workloadsimultaneously increases myocardial oxygen consumption. This should be concerned in an individual suffering from cardiac disease, particularly given that the beneficial coronary vasodilator effect of epinephrine is diminished or absent in the presence of coronary vessel atherosclerosis. Those risk to the cardiac patient is the potential of epinephrine to irritate cardiac pacemaker cells and results in dysarhythmias. Thus, the imprudent use of epinephrine can be harmful to a patient with cardiac disease.[2]

EpinephrineIn Dentistry

Epinephrine is a commonly used drug in cases of medical emergency situation. In case of dentistry, it has two uses. First, it is a constituent of local anesthetic solution commonly used in dentistry. Secondly, it is used as a haemostatic agents in gingival retraction cord[3].Though epinephrine have these use, which may not be as readily achievable through use of non-epinephrine preparations, the clinical impact of cardiovascular and hemodynamic changes caused by the introduction of exogenous epinephrine makes its use among hypertensive

individuals has some controversies in dentistry. The added risks produced by the use of epinephrine in hypertensive patients include:

- Through the action of epinephrine-greater probability of acute hypertensive crisis (seriously high blood pressure), angina pectoris and myocardial infarction, as well as cardiac arrthymias.
    - Risk of drug interaction of epinephrine and some antihypertensive medication can lead to acute hypertensive or hypotensive crisis.[4]

      Administrating epinephrine in patients should be done with care as a frequent monitoring of blood pressure is essential because of its pharmacological actions. Epinephrine produces two types of effects in patients. One effect is pronounced on heart due to its beta-1 effects and other effect is on skeletal muscle blood vessels due to its beta-2 effects. This results in increased blood pressure and heart rate. [5]

Hypertension

Hypertension is one of the most frequently encountered systemic diseases in patients visiting dental clinics, due to its high prevalenceworldwide. It is defined as the values greater than 140 mmHg SBP (Systolic Blood Pressure) and values greater than 90 mmHg DBP (Diastolic Blood Pressure).It is also called as “Silent Killer” because it often affects target organs such as brain, heart, kidneys, eyes etc before the appearance of clinical symptoms. A permanent high blood pressure affects blood vessels in heart, kidney and brain which increases the chances of renal ,coronary heart disease and stroke.[6]JNC 7 introduces a category called “prehypertensive” to describe people with SBP of 120 to 139 mm Hg or a DBP of 80 to 89 mm Hg. People with prehypertension are at increased risk of progressing to hypertension and require health- promoting lifestyle modifications to prevent CVD.[7] One of the reasons that the concept of pre- hypertension was developed is to provide a wake-up call for affected people to encourage them to make appropriate lifestyle choices. A critical aspect in the prevention and management of hypertension is the adoption of healthy lifestyles. Without lifestyle modifications, BP may not be controlled adequately despite sufficient doses of antihypertensive drugs or appropriate combinations of drugs. Recommended modifications are weight reduction for overweight patients, dietary sodium reduction, appropriate physical activity and moderation in consumption of alcohol. Also, the consumption of a diet rich in

fruits, vegetables and low-fat dairy products such as recommended in the Dietary Approaches to Stop Hypertension. [8, 9]

A greater of awareness on hypertension recorded in the present study could be due to the lifestyle and some other factors compared to the general population. The risk factors associated with hypertension are similar to that seen in other studies which were done in general population. So health-care providers should recognize the increased risk of prehypertension and should seek to identify and treat the modifiable risk factors in these persons especially among undergraduate students who are country's young generation. [10]

Etiology, Classification And Pathogenesis Of Hypertension

Hypertension is the most common primary diagnosis in the United States, affecting more than 50 millionsPopulations and also in developing countries like India and China. Etiological factors correlated with hypertension in adults have also been associated with blood pressure elevations in youth. Intrauterine malnutrition, family history of hypertension ,obesity, particularly excess abdominal fat, insulin resistance, high dietary sodium intakes, low dietary intakes of calcium, potassium and magnesium, physical inactivity, high alcohol intakes, tobacco use, drug use (e.g., cocaine, ecstasy, anabolic steroids), emotional stress, diet pill use, oral contraceptives are the factors associated with development of hypertension.[11]

Hypertension is classified as primary or essential hypertension and secondary hypertension. Primary hypertension is most common form of hypertension where the level of hypertension is medium to high for a long time without a known cause. [12]Secondary hypertension is the one which occurs with an organic cause which includes renal, endocrine, neurological and others such as drugs induced, pregnancy toxaemia etc.JNC 7 introduced in 2003 the category of prehypertension in which the patients with this condition are at increased risk of developing hypertension. [13]Pathogenesis of hypertension results from a complex interaction between genetic factors and the environment. Some of them are age, family history of premature cardiovascular disease, smoking, increased consumption of alcohol, cholesterol rich diet. [14]

Table: 1 Showing classification of Hypertention

Classification	SBP (mmHg)	DBP (mmHg)
Normal	<120	And <80
Prehypertension	120-139	Or 80-89
Stage I hypertension	140-159	Or 90-99
Stage II hypertension	>160	>100

HypertensionAnd Cardiovascular Disease

Hypertension is found to have alink in many cardiovascular diseases. Some of them are

Arterial hypertension is an important health problem as it causes risks of cardiovascular diseases such as chest pain,myocardial infarction and cerebrovascular event. [15] In such cases, patient's blood pressure is frequently monitored before dental treatment to make the blood pressure under control to manage this condition. Heart failure is defined as incapacity of heart to function properly, pumping insufficient blood towards the tissues and leading to fluid accumulation within the lungs, liver and peripheral tissues. It is of two types.

I. Acute heart failure: The most common causes of heart failure are severe and prolonged arterial hypertension, valve disease and ischemic heart disease. This typically manifests as acute lunge enema.[16]
II. Chronic heart failure: The most common cause of this type of heart failure is that this is also associated with arterial hypertension.

Hypertensive Emergency: It is defined as elevated BP with signs and symptoms of target organ damage. The blood pressure should be acutely lowered or else tissue perfusion in brain heart can occur which is regulated by MAP (meanarterial pressure). [17, 18, 19]

Epinephrine And Associated Risk Of Cardiovascular Disease

Various studies have revealed the fact that diastolic blood pressure decreased and heart rate increased in both normotensive and hypertensive patients during dental treatment with epinephrine containing local anesthetic. These changes were small and unlikely to be clinically significant. Systolic blood pressure rose slightly in hypertensive patients but not in

normotensive individuals when Epinephrine containing local anaesthetics were injected, this was proved by vet ale et al in 1960's [20].He stated that patients who received lidocaine with epinephrine and underwent subsequent tooth extraction presented clinical evidence of diminished postoperative bleeding from the socket wound. This was determined from the condition of the gauze sponges placed over the sockets. In addition, the patients so studied attested to the depth and duration of anaesthesia produced. It has been stated many times in the past that the use of local anesthetic solutions without epinephrine is unrealistic since the oral operations that follow are often associated with pain. This pain, in turn, will produce more epinephrine from natural secretion (adrenal medulla) than does the 1:50,000 or 1: 100,000 epinephrine normally used in local anesthetic solutions. It is true that depth of anaesthesia is desirable. However, as has been demonstrated in twenty-six. Patients, both normotensive and hypertensive, an anesthetic properly placed by infiltration or by the block method will produce satisfactory anaesthesia for routine dental procedures within five minutes. The pressor response related to fear of the injection and the impending dental surgery was so evident in this experiment, and also in those reported by Cheraskin and Prasertsuntarasai, that premeditation should become routine. When local anaesthesia for dental procedures involving trauma is anticipated for patients with hypertension, cardiovascular disease, and anxiety states. These patients are greater operative risks, and care should be taken to see that their physical abnormalities are recognized. The care of patients with this type of abnormalities needs a close cooperation between the physician and the dentist. Anxiety, pain, fear, or prolonged traumatic operation should be avoided. Adequate preoperative medication, usually with barbiturates as the drugs of choice is therefore important to ensure a smoother and safer surgical procedure.

Management

While managing a hypertensive patient in the dental office, the dentist must take efforts to perform the dental procedures with optimum pain control, reduced stress and anxiety. To perform a safe dental procedures in hypertensive patients, the operator must follow certain guidelines. Dentist must monitor the blood pressure carefully before and after the administration of local anaesthesia. Pre operative reassurance with the use of effective local anaesthesia (with or without epinephrine) may help in alleviating the related anxiety and reduced the chances of increased blood pressure. The risky patients should be advised to seek

medical attention, during the dental treatment. Epinephrine can be used in management of hypertension by giving two 1.8 ml cartridges of lignocaine containing 1:100,000 epinephrine which is considered as safer dose for these hypertensive patients. [21]

In 1964, a Working Conference of the American Dental Association and the American Heart Association 18stated that the concentrations of vasoconstrictors normally used in dental local anaestheticsolutions were not contraindicated in patients with cardiovascular disease when administered carefully and with preliminary aspiration.Malamed recommended a much smallermaximal dose of vasoconstrictor (no more than 40 µgof epinephrine at one appointment) for patients with severe cardiovascular disease. Little etepinephrine (18 to 36 µg of epinephrine) were of little clinical significance to most patients with hypertension or other cardiovascular diseases [22]. Kaneko21 recommended that the total dose of epinephrine should be limited to less than 40 µg in moderate cases or 20 µg in serious cases, with epinephrine concentrations of 1:100,000 or less. Current clinical practice has tacitly accepted the safety of epinephrine use in patients with cardiovascular disease. Therehave been several reports of the hemodynamic effects of epinephrine in patients with cardiovascular disease. Cintron et alreported that dental anaesthesia with 1.0 ml of 2% lidocaine with 1:100,000 epinephrine caused no significant changes in HR or blood pressure and was well tolerated by patients with recent myocardial infarction. Middlehurst and Coulthard reported that approximately 5 ml of 2% lidocaine with 1:50,000 epinephrine and 0.25 IU/ml of vasopressin did not cause ischemic changes in patients with heart disease. Davenport et al studied the hemodynamic effects of moderate doses of epinephrine during periodontal surgery in patients with stable cardiovascular disease and found no significant changes in HR or blood pressure, despite the elevation of the plasma epinephrine concentration. Whenexcessive concentration or dose of epinephrine is administered in patients with a normal heart, SV and cardiac output are further elevated because of the β1 effect of epinephrine, leading to a prominent rise in blood pressure. Consequently, rate pressure product, indexes of myocardial oxygen consumption, and left ventricular stroke work (the product of MAP and SV), representing the level of work by the left ventricle, also increase. Although a normal heart can apparently withstand these great demands, in failing or ischemic heart, cardiac functions may be impaired by these changes. The possibility of adverse interactions between epinephrine and nonselective β-blocking agents has been suggested. Epinephrine production may lead to an exaggerated increase in blood pressure in patients taking a nonspecific β-blocking agent such

as propranolol. As shown in Fig 1, the response to the low dose of epinephrine in patients taking nonselective β-blocking agents differed from that in patients not taking such medication. Little suggested, on the basis of clinical experience, that 1:100,000 epinephrine (no more than 0.036 mg of epinephrine) in a local anesthetic could safely be used for patients receiving nonselective βblocking agents. However, the possibility of a hypertensive interaction occurring with epinephrine should be considered when epinephrine is used in patients taking a nonspecific β-blocking agent. This study provides documentation that 1.8 ml of L-E is safe and has few, if any, hemodynamic consequences in patients with cardiovascular disease. We concluded that a low dose of epinephrine (22.5 µg) in local dental anaesthesia was well tolerated by cardiovascular patients. [23]

Conclusion

Dentistry has played a cardinal role in the detection of patients with hypertension. Patients suspected to have high blood pressure should be referred to medical diagnosis. In dental office medical emergencies do occur to which dentist has to be prepared to overcome those difficulties. An early detection of hypertension by the dentist can lead to prompt treatment in the dental office.

Cigarette Smoking, Endothelial Injury and Cardiovascular Disease

Benazir HussainM[1], Sivakumar M[2]

Graduate Student[1], Senior Lecturer[2], Department of Oral and Maxillofacial Surgery

Saveetha Dental College, Saveetha Institute of Medical and Technical Science, Saveetha University, Chennai, India

Abstract

Despite the fact that the epidemiological evidence linking cigarette smoking with cardiovascular disease is overwhelming, the precise components of cigarette smoke responsible for this relationship and the mechanisms by which they exert their effect have not yet been elucidated. There are however, some promising pointers as a result of recent developments and this review concentrates on new evidence since earlier reviews of this topic. It is now known that the endothelium has a vastly more important role than was ever thought to be the case a decade ago. Its role in health and disease is increasingly understood, as is the relationship between endothelial injury and the development of atherosclerosis. There is considerable evidence that cigarette smoking can result in both morphological and biochemical disturbances to the endothelium both *in vivo* and in cell culture systems. Cigarette smoke is a complex mixture and only a few components have been extensively studied. Nicotine and carbon monoxide are much less damaging than is whole smoke. However the free radical components of cigarette smoke have been shown to cause damage in model systems. Further work will be necessary to consolidate the evidence base but the data reported in this review suggest that the free radical components of cigarette smoke may be responsible for the morphological and functional damage to endothelium that has been observed in model systems. This reviews gives a detailed description on effect of smoking in heart and cardiovascular system

Key Words: *cigarette smoking, endothelium, injury, nicotine, carbon monoxide, free radicals, morphology*

Introduction

Death from coronary heart disease is more common in smokers than nonsmokers were published in the 1950s,[1] there have been many reports which convincingly demonstrate that cardiovascular disease is the most important cause of smoking-related premature death.[2] The prospective investigation of British Doctors commenced in 1951 showed that half the excess mortality from smoking results from cardiovascular disease with approximately one third due solely to coronary heart disease. Prospective studies on smokers have shown that the risk of death from coronary heart disease is roughly doubled for both men and women although there is evidence that the risk is greater for women estimated that cigarette smoking accounted for 25% of the overall mortality from ischaemic heart disease. More recently in the United States, has estimated that one fifth of all heart disease-related deaths are due to cigarette smoking and that smoking, as a single factor, doubles the risk of heart failure.[3] Cigarette smokers are also one and a half times more at risk of stroke than nonsmokers. Cigarette smoking is an independent risk factor in the development of atherosclerotic lesions in the internal pudendal and common penile arteries of young impotent men.[4] It is a significant predictor of the presence of intracranial internal carotid artery atherosclerosis. In the Edinburgh Artery Study, cigarette smoking was shown to have a direct effect on the risk of aortic aneurysm which was independent of atherosclerosis. This review also showed that smoking increases the risk of peripheral artery disease more than heart disease. Perhaps not surprisingly, cigarette smokers who regularly undertake physical activity have a reduced cardiovascular mortality rate than those who have a sedentary existence. Increased total exposure to tobacco in humans and a smoking pattern which maximizes nicotine yield are also associated with an increased risk of peripheral arterial disease.[5]

Endothelial Injury

Despite the strong epidemiological evidence that exists linking cigarette smoking and cardiovascular disease, the mechanisms by which cigarette smoking causes disease and the components of smoke responsible remain poorly understood. Endothelial injury is considered to be a key initiating event in the pathogenesis of atherosclerosis and it has therefore seemed reasonable to hypothesize that cigarette smoke, or some components of it, may exert its effects by damaging the endothelium.[6] Components of smoke that gain access to the circulation will come in contact with blood and with the vascular endothelial cells that form a monolayer lining the vessels. These cells are now known to have a crucial role in controlling

the blood circulation and to be highly active metabolically. Even minor disturbances to their normal functioning could have significant implications for the initiation and development of atherosclerosis. Endothelial functions, including an increase in permeability and decreased nitric oxide (NO) production along with increased expression of adhesion molecules and adherence of leukocytes to the vessel wall, have been shown to be impaired by risk factors for cardiovascular disease such as hypertension, hyperlipidaemia and hyperglycaemia.[7] This review examines the evidence that cigarette smoking can bring about vessel wall damage with particular reference to the vascular endothelium.

Damaging Effects of Cigarette Smoking on Human Arteries

Direct evidence that cigarette smoking can result in atherosclerosis continues to be obtained from human investigations. Using serial quantitative coronary arteriography, have shown that cigarette smoking accelerates coronary progression and new lesion formation.[8] Interestingly, Lovastatin was shown to slow the progression of coronary atherosclerosis and prevent the development of new coronary lesions in smokers. The relative thickness of the intima and media of an artery as measured by ultrasound can be used to provide an index of atherosclerosis. Carotid artery atherosclerosis determined by ultrasound determination of plaque thickness, a measure of atherosclerosis, is accelerated depending on the level of cigarette use and this is independent of age, hypertension and diabetes.[9] Cigarette smoking has an adverse effect on the intimal medial ratio and stenosis of the carotid artery as measured by ultrasound. Exposure to environmental tobacco smoke (passive smoking), and cigarette smoking have been shown using the intimal/medial ratio as an index to cause progression of atherosclerosis in the carotid artery. Cigarette smoking was shown to be an independent indicator of the severity of coronary and thoracic aortic atherosclerosis in men receiving coronary angiography and transoesophageal echocardiography.[10] In uraemic patients on chronic dialysis cigarette smoking is associated with carotid atherosclerosis as revealed using echo-colour-Doppler evaluation. Studies on the coronary arteries of trauma victims aged between 15 and 34 years of age suggest that intermediate atherosclerotic lesions progress rapidly into advanced lesions in smokers and that intima formerly having early lesions is replaced by intima with raised lesions.[11] This study also demonstrated that smoking was associated with more extensive fatty streaks and raised lesions in the abdominal aorta. Radiological observations on women aged between 45 and 64 years showed a direct association between the development of calcified deposits, which have been shown to represent atherosclerotic change, in the abdominal aorta and the number of cigarettes smoked

per day over a nine year period.[12] This study suggests that the rate of atherosclerotic change may be reduced by the cessation of smoking, but a residual effect appears to be present for a decade. Using ultrasonography to look at carotid intima and media thickness, the evidence indicates that atherosclerosis is mediated by components of tobacco smoke other than nicotine.[13]

Cigarette Smoking and Endothelial Modification

Direct evidence that cigarette smoking could result in endothelial injury was first obtained from morphological observations on the umbilical arteries from smoking mothers. These reports, along with others on the effects of cigarette smoking on endothelial morphology, have been previously reviewed by Pittilo (1988,1990). The morphological alterations, which included the endothelium having an irregular appearance along with membrane disturbances evidenced by the formation of blebs or microvillous-like projections, were also associated with functional changes to the endothelium. In laboratory rats exposed to cigarette smoke were able to demonstrate that the morphological alterations to the endothelium of the thoracic aorta were accompanied by reduced endothelial prostacyclin production as well as the adhesion of platelets to apparently intact cells.[14]

Cigarette Smoking and the Components of Smoke Responsible for Endothelial Injury

Cigarette smoke is a complex mixture and only a few components have been examined in isolation to assess their effects on endothelial morphology and function. The effects of nicotine on both the morphology and prostacyclin production of rabbit and cultured human endothelial cells has been reviewed by Bull (1988),Pittilo (1990) and Woolf *et al*. (1993), and although deleterious effects result from exposure, these are much more limited than those observed with whole smoke.[15] Clinical studies support these findings in that observations on pipe smokers and users of transdermal nicotine devices suggest that components of smoke other than nicotine are the most important causes of acute cardiovascular events. The effects of carbon monoxide exposure have also been reviewed and are conflicting, with some reports providing evidence of morphological or functional alterations and others reporting no effects.[16]

Rats exposed to nicotine show an increased frequency of endothelial cell death which results in enhanced transendothelial leakage of macromolecules including low density lipoproteins. Nicotine has been shown to enhance the release of platelet-derived growth factor by bovine

aortic smooth muscle cells and is associated with alterations in the cytoskeleton. Nicotine significantly stimulates DNA synthesis and endothelial cell proliferation in bovine pulmonary artery endothelial cells at concentrations lower than those obtained in the blood after smoking.[17] In rabbits, administration of nicotine is associated with an acceleration of intimal hyperplasia following endothelial removal.

Data derived from epidemiological and animal studies suggest that carbon monoxide is not atherogenic. However, exposure of cockerels to carbon monoxide does not have a discernible effect upon arteriosclerotic plaque development. Bovine pulmonary artery endothelial cells exposed to carbon monoxide release higher concentrations of nitric oxide and it has been suggested that carbon monoxide causes oxidative stress through competition for intracellular binding sites which increase steady state levels of nitric oxide and the generation of peroxynitrite by the endothelium.[18] Carbon monoxide suppresses the production of endothelin-1 and platelet-derived growth factor B by endothelial cells.

There is experimental evidence with cockerels to indicate that exposure to environmental tobacco smoke at levels equivalent to those routinely encountered by people in smoke-filled environments is sufficient to promote arteriosclerotic plaque development. In cholesterol-fed rabbits, passive smoking increases aortic and pulmonary artery atherosclerosis in a dose-responsive way and is independent of changes in serum lipids. One review of the literature concluded that passive smoking increases platelet activity, accelerates atherosclerotic lesion formation, and increases tissue damage following ischaemia or myocardial infarction.[19] However, it has been argued that the available experimental and epidemiological evidence to date does not support an association between environmental tobacco smoke exposure and an increased risk of heart disease.

Woolf *et al*. (1993) and Pittilo& Woolf (1993,1994) focused on the possible importance of free radicals as the mediator of cigarette smoke-induced endothelial damage for a number of reasons. Cigarette smoke has been known for many years to be a rich source of free radicals. The scanning electron microscope changes seen in laboratory rats following smoke exposure, or cultured cells following exposure to plasma from humans after smoking, were similar to the changes seen in cardiac myocytes following free radical-induced lipid peroxidation.[20] Finally, there is a strong association between lipid peroxidation and endothelial cell injury were reviewed some of the supportive evidence and considered that free radical-induced lipid peroxidation might eventually be shown to be the mechanism responsible for the

epidemiological relationship between cigarette smoking and atherosclerosis.[21] It has been suggested that the high levels of lipid peroxidation and increased formation of reactive oxygen species within the vascular wall in atherosclerosis can overwhelm cellular antioxidant defence mechanisms and human oxidatively modified LDL-induced expression of antioxidant stress proteins in vascular cells.

On the contrary, studies showing no differences in free radical markers between smokers and nonsmokers suggest that any free radical activity generated from smoking is adequately scavenged. No significant differences in free radical markers were found between young adult smokers and nonsmoking volunteers. Free radical activity due to cigarette smoking also appears to be adequately scavenged in young adults with diabetes who are free of significant macrovascular disease.[22] Furthermore, there is evidence to indicate that chemical modification of glutathione is a major damage mechanism of filtered cigarette smoke with free radical oxidations being less significant.[23]

Despite these findings, there remains strong evidence to implicate free radicals as an important cause of cigarette smoke-induced endothelial injury. The morphological alterations seen with cultured cells exposed to plasma obtained from volunteers after smoking are associated with functional changes to the endothelium including activation of the hexose-monophosphate shunt, a sharp increase in the total glutathione content of the culture medium, release of angiotensin-converting enzyme from the cells and a decrease in the ability of the cells to produce ATP, all of which indicate both oxidative stress and cell injury. Smoking is also a major determinant of increased plasma-free radical activity in dyspeptic subjects.[24]

Free Radicals and Cigarette Smoke

Cigarette smoke consists of two distinct populations of free radicals; the principal free radical in the tar phase is a quinone/hydroquinone (Q/QH_2) complex which is an active redox system that can reduce molecular oxygen to produce superoxide, and in the gas phase small oxygen-centred and carbon-centred radicals produced in a steady state by the oxidation of nitric oxide (NO) to nitrogen dioxide (NO_2) react with reactive species in smoke such as isoprene.[25] The radicals associated with the particulate or tar phase of cigarette smoke are long lived whereas the radicals associated with the gas or vapour phase have structures that predict a very short lifespan, although spin trap experiments demonstrate that these radicals may exist for periods in excess of five minutes. Aqueous extracts of cigarette tar auto-oxidize to

produce semiquinone, hydroxyl, and superoxide radicals in air-saturated buffered aqueous solutions.[26]

Direct-electron resonance measurements suggest that superoxide and hydroxl radicals are produced during the auto-oxidation of hydroquinone and catechol-related species in aqueous extracts of cigarette tar. Fresh cigarette smoke contains from 300 to 500 parts per million of nitric oxide. The nitric oxide radical is produced slowly from nitric oxide radical donors such as amine complexes, peroxinitrite and other reactants including nitrogen oxides. Nitric oxide can react with hydrogen peroxide to produce singlet oxygen which may also be important in mediating cigarette smoke-induced endothelial damage. Certainly there is evidence to suggest that nitric oxide in cigarette smoke is important as a mediator of oxidative damage and that DNA damage by cigarette smoke may invoke reactive nitrogen species as well as reactive oxygen species.[27] Analysis of cigarette smoke demonstrates that the main source of oxygen and hydrogen peroxide results from polyphenols in the particulate phase, and a synergistic effect is observed between these polyphenols and nicotine. The vapour phase contains a factor which produces reactive oxygen metabolites from hydrogen peroxide. Free radicals in the gas phase of cigarette smoke, identified using electron spin resonance spectrometry, were identified as mainly alkoxyl and alkyl free radicals with the latter making up approximately two thirds of the total spectral components.[28]

Haemoglobin-impregnated conventional cigarette filters are capable of withholding nitric oxide, nitrogen oxides, hydrogen peroxide, carbon monoxide, aldehydes, trace elements and carcinogenic nitrosocompounds from cigarette smoke.[29] This is interesting in view of the fact that the red blood cells of cigarette smokers contain more glutathione than those of nonsmokers and are more protective to endothelial cells in culture from hydrogen peroxide-mediated damage than are the red cells from nonsmokers.[30]

Cigarette Smoking and Endothelial Dysfunction

More recent studies that have not been the subject of previous reviews continue to provide evidence that cigarette smoke can alter vascular endothelium not only morphologically but functionally. In recent years, the discovery of nitric oxide has radically altered our understanding of vascular control.[31] Both nitric oxide and carbon monoxide generated within the blood vessel wall are important cellular messengers involved in the regulation of vascular smooth muscle tone. Carbon monoxide generated through haeme oxygenase inhibits mitogen-induced proliferation of vascular smooth muscle cells and there is evidence that

endogenous carbon monoxide serves as a protective factor limiting the excessive vascular smooth muscle cell proliferation associated with vascular disease.[32]

Cigarette smoking is associated with dose-related and potentially reversible impairment of endothelium-dependent arterial dilation in asymptomatic young adults, consistent with endothelial dysfunction. It augments endothelial-derived vaso relaxation but has no effect on endothelium-independent vaso relaxation.[33] It leads to a significant decrease in endothelium-dependent dilatation of the brachial artery. It causes immediate constriction of proxymal and distal epicardial coronary arteries and an increase in coronary vessel tone despite an increase in myocardial oxygen demand, and cigarette smokers show an impairment in basal but not stimulated nitric oxide mediated vaso dilation.[34]

Cigarette smoking has been shown to affect endothelial nitric oxide synthase activity and protein levels. It results in a decrease in exhaled nitric oxide in humans suggesting that it may inhibit the enzyme nitric oxide synthase. Cigarette smoke extracts cause an irreversible inhibition of nitric oxide synthase activity in pulmonary artery endothelial cells and a reduction in constitutive nitric oxide synthase activity in the rat in a dose-dependent manner.[35] Conversely, other studies in the rat have shown that cigarette smoking results in an increase in nitric oxide synthase gene expression and protein production. However, lower respiratory tract nitric oxide concentrations are increased following cigarette smoking although, in humans, plasma and urinary levels of nitrate, a metabolite of inhaled nitric oxide, have been shown to be unchanged suggesting that nitric oxide is not absorbed from the inhaled smoke.[36]

Inhibition of nitric oxide synthase activity may explain the impaired endothelium-independent vasodilation associated with cigarette smoking. The decrease in endothelial nitric oxide synthase activity may also partly explain the high risk of pulmonary and vascular disease in cigarette smokers. Cigarette smoking affects nitric oxide-mediated coagulation of coronary artery tone which is associated with a decrease in the bioactivity of nitric oxide.[37] It has been shown to increase isoprostane levels and reduce the generation of prostacyclin, l-arginine and l-citrulline in umbilical arteries and veins, and correlates with a direct vasoconstrictive effect. Chronic smoking in the rat leads to age-independent moderate hypertension and a decrease in penile nitric oxide synthase activity.[38]

It has been reported that exposure of cultured bovine pulmonary artery endothelial cells to carbon monoxide results in increased release of endothelial nitric oxide. The acute

cytotoxicity from carbon monoxide was owing to nitric oxide-derived oxidants. Incubation of isolated rabbit aortas with cigarette smoke extract inhibits endothelium-dependent relaxation in a dose-dependent manner.[39] If this incubation is carried out with free radical scavengers, attenuation of the inhibition occurs. This suggests that free radicals in cigarette smoke extract induce the impairment of endothelium-dependent relaxation and this may be partly because of the suppression of nitric oxide production. The same author has demonstrated, using cultured human endothelial cells, that cigarette smoke extract suppressed endothelial release of stable metabolites of nitric oxide and this was attenuated by free radical scavengers. The superficial femoral veins from rabbits exposed to cigarette smoke have a significant decrease in endothelium-dependent relaxation in response to acetylcholine without smooth muscle injury.[40] Ascorbic acid protects rabbit arteries from cigarette smoke-induced endothelial injury by reducing the impairment of endothelium-dependent acetylcholine relaxation caused by smoking, probably as a result of oxygen-free radicals.[41]

It has been suggested that the presence of hypoxia and exogenous nitric oxide, which lead to endothelial-dependent and independent vaso-relaxation secondary to cigarette smoking, may serve to explain the apparent augmentation of endothelial-derived relaxation in the rat. Cigarette smoking has been shown in the rat to increase aortic endothelial regeneration and serum levels of nitric oxide following balloon injury of the thoracic aorta.[42] Acute hypoxia causes pulmonary vessel constriction, and chronic hypoxia causes smooth muscle cell replication and extracellular matrix accumulation, resulting in vessel wall remodelling. Oxidized low-density lipoprotein, hypoxia and pro-inflammatory cytokines induce haem oxygenase expression and activity in vascular endothelial and smooth muscle cells.[43]

Cultured human umbilical endothelial cells from smokers convert significantly more LDL into an atherogenic form than do cells derived from nonsmokers. The LDL modifications were strongly thiol-dependent and the enhanced superoxide production seen in the cells derived from smokers was dependent on the presence of cysteine in the medium.[44] There is also evidence that cigarette smoking results in endothelial dysfunction in hypercholesterolemic patients by enhancing the oxidation of LDL. Cigarette smoke-modified low-density lipoprotein has been reported to impair endothelium-dependent relaxation in isolated rabbit arteries.[45]

Cells derived from smokers have higher levels of intracellular glutathione than those from nonsmokers and it may be that stimulation of cysteine uptake by the cells reflecting the

enhanced total glutathione content could account for the enhanced superoxide production, all of which may be relevant to the pathophysiology of smoking-related cardiovascular disease. It has already been noted that there is evidence to indicate that chemical modification of glutathione is a major damage mechanism of filtered cigarette smoke with free radical oxidations being less significant. Endothelial cell cGMP production is decreased in a dose-dependent manner following cigarette smoking and endothelial cell detachment is increased following smoking.[46] Externally added thiols protect endothelial cells from damage and it has been suggested that they may bind an unknown component of smoke to bring about this protection. In humans, the endothelial dysfunction observed following cigarette smoking lasts for about one hour and is not attenuated with repeat exposure.[47]

Cigarette smoking is associated with increased monocyte-endothelial cell adhesion in humans. Studies on hamsters using intravital microscopy and scanning electron microscopy demonstrate that cigarette smoking results in leucocytes adhering in clusters to the aortic endothelium and that aggregates of leukocytes and platelets are formed.[48] There is evidence that phagocytes may employ myeloperoxidase-generated reactive nitrogen intermediates as a physiological pathway for initiating lipid peroxidation as well as forming biologically active lipid and sterol oxidation productions *in vivo*.[49] Increased generation of oxygen free radicals by polymorphonuclear leucocytes may be responsible for the enhanced risk of certain smoking-related diseases. The promotion of neutrophil infiltration and free radical production in rats exposed to cigarette smoke has been shown to contribute significantly to the development of experimental inflammatory bowel disease.[50]

Cigarette smoking has been shown to increase re-endothelialization in the rat following large vessel injury and this is associated with an increase in serum nitric oxide levels. There is evidence that cigarette smoke-induced cell proliferation in the pulmonary arterial vessels is partly mediated through stimulation of endothelin-A receptors.[51] Conversely, cigarette smoke represses angiogenesis in the rat. Cigarette smoking, but not transdermal nicotine delivery, is associated with borderline increases in plasma endothelin-1 levels but these are restricted to the first 10 minutes after the onset of smoking.[52]

In a study of monozygotic twins discordant for smoking found that cigarette smoking was associated with an atherogenic lipid profile along with changes in platelets and white cells which might reflect endothelial cell damage. Cigarette smoking increases total serum cholesterol levels.[53] Smokers have mean serum levels that are higher than nonsmokers for

total and low-density lipoprotein cholesterol and triglyceride whereas high-density lipoprotein cholesterol levels are lower. There is evidence that cigarette smoking results in increased platelet consumption in human atherosclerotic vessels as well as the production of larger platelets which are more active.[54] Cigarette smoking causes marked inhibition of substance P-induced tissue plasminogen activator released *in vivo* in humans. Serum from cigarette smokers contains higher levels of von Willebrand factor and was more cytotoxic to endothelial cells *in vitro* than serum from nonsmokers.[55]

Conclusion

Since the publication of previous reviews on cigarette smoking, endothelial injury and cardiovascular disease, there have been new reports that demonstrate that cigarette smoking is associated with blood vessel wall damage including endothelial injury. Cigarette smoke is a complex mixture containing a range of individual components and only a small number of these have been examined in isolation. Whilst components such as nicotine and carbon monoxide have been the subject of a number of investigations, their damaging effects in model systems are less than those seen with whole smoke. Free radicals are an important component of cigarette smoke and our understanding of their chemistry and effects on biological systems has greatly increased. It seems likely that they will be further implicated as critical to the link between cigarette smoking and cardiovascular disease.

Abstract

Cleft lip which is known as ancheiloschisis and cleft palate which has an other name of palatoschisis, which can also occur together as cleft lip and palate, are variations of a type of clefting congenital deformity caused by abnormal facial development during gestation. A cleft is a fissure or opening—a gap. It is the non-fusion of the body's natural structures that form before birth. In past, the condition was referred asan harelip, based on the similarity to the cleft in the lip of a hare, but that term is now generally considered to be offensive. Clefts can also affect other parts of the face, such as the eyes, ears, nose, cheeks, and forehead. Most of these craniofacial clefts are rare and are frequently described as Tessier clefts using the numerical locator which was coined byTessier. A cleft lip or palate can be successfully treated with surgery, especially so if conducted soon after birth or in early childhood.

Key Words: *Congenital deformity, velopharyngeal inadequacy, van der won syndrome,*

Introduction

Cleft lip is formed within the top of the lip as either small low gap or an indentation within the lip which is an partial or incomplete cleft when it continues into the nose it is known as an complete cleft. Lip cleft will occur as a 1 sided (unilateral) or 2 sided (bilateral). It's due to the failure of fusion of the jaw and medial nasal processes (formation of the first palate) congenital abnormality could be a condition during which the 2 plates of the bone that type the surface (roof of the mouth) don't seem to be fully joined. The soft palate is in these cases

cleft as well. In most cases, cleft lip is additionally present. congenital abnormality happens in concerning one in 700 live births worldwide

Cleft Lip

The cleft doesn't have an effect on the palate structure of the mouth it's named as birth defect. It is a kind of birth defect may be a microform cleft.[1] A microform cleft will seem as little as a bit dent in the red a part of the lip or appear as if a scar from the lip up to the nostril.[2] In some cases muscle tissue within the lip beneath the scar is affected and would possibly need surgery.[3] it's suggested to own newborn infants with a microform cleft checked with a craniofacial team as presently as attainable to work out the severity of the cleft.[4]

Cleft Palate

Palate cleft will occur as complete (soft and surface, presumably including a gap in the jaw) or incomplete (a 'hole' within the roof of the mouth, sometimes as a cleft soft palate). once birth defect happens, the flap is sometimes split. Cleft palate happens due to the failure of fusion of the lateral palatine processes, the septum, and/or the median palatine processes, that is failure in the formation of the secondary palate.The hole within the roof of the mouth caused by a cleft connects the mouth on to the cavum. AN open affiliation between the oral fissure and nasal cavity is named velopharyngeal inadequacy (VPI). due to the gap, air leaks into the cavum leading to a hypernasal voice resonance and nasal emissions whereas talking. possible treatment choices include therapy, medical specialty, augmentation of the posterior pharyngeal wall, lengthening of the surface, and surgical procedures.(5)

Cleft Lip and Palate

The primary palate has the following structures lip, alveolus, and anterior palate back to the incisive opening. The secondary palate consists of the exhausting and soft palates from the incisive opening back to the flap. The birth defect includes feeding difficulties, issues regarding to speech development, and therefore the chance of impaired facial growth. The breadth of a primary roof of the mouth cleft and therefore the degree of collapse square measure usually inflated within the presence of a cleft of the secondary roof of the mouth. The family is recommended concerning the anticipated inflated range of surgical operations which will be needed if a birth defect is present: primary birth defect repair with intravelarveloplasty; potential secondary surgery on the palatopharyngeal muscle sling, similar to a sphincteroplasty or tubular cavity flap; and potential orthognathic surgery at

skeletal maturity. The abnormal attachment of the muscles of the taste bud during a birth defect alters the strain on the tubular cavity voidance of the eustachian canal, increasing the incidence of ear infections. surgery and eyelet tube placement is performed within the majority of infants at the time of either the lip repair or the roof of the mouth repair to forestall the event of hearing abnormalities

Genetics of Cleft Lip and Palate

Cleft of the lip or palate is caused by several etiological factors. In massive of the causes they're caused by single mutant genes, some by chromosomal aberrations, some by environmental agents, and a few by interaction between the genetic and environmental variations. The first, second and third branchial arches play a vital role within the development of the face, mouth and tongue. The event of the face is well represented in terms of its formation and merging of varied processes or prominences. The frontonasal and jaw processes grow downward and forward however the mechanism of this interaction and its coordination is unclear. The secondary roof of the mouth could be a structure that separates the nasal passage from the oral fissure. The roof of the mouth correct develops from each primary and secondary elements. Sub-clinical phenotypes will embrace minor structural variants together with lip pits/prints, (6) dental anomalies,(7) defects of the orbicularis oris muscle,(8,9,10) facial image measure, brain variants as assessed by MRI(11,12)

Epidemiology and Etiopathogenesis

Among the cleft lip and surface population, the foremost common identification is cleft lip and surface at forty sixth, followed by isolated congenital anomaly at thirty third, then isolated cleft lip at twenty first. the bulk of bilateral cleft lips (86%) and unilateral cleft lips (68%) area unit related to a congenital anomaly. Unilateral clefts area unit nine times as common as bilateral clefts, and occur double as often on the left aspect than on the correct. Males area unit predominant within the harelip and surface population, whereas isolated congenital anomaly happens additional unremarkably in females. within the white population, cleft lip with or while not congenital anomaly happens in just about one in one,000 live births. These entities area unit double as common within the Asian population, and just about [*fr1] as common in African Americans. This racial nonuniformity isn't determined for isolated congenital anomaly, that has an overall incidence of zero.5 per 1,000 live births. each environmental teratogens and genetic factors area unit concerned within the genesis of cleft lip and surface. Intrauterine exposure to the medicament hydantoin is related to a 10-fold

increase within the incidence of cleft lip. Maternal smoking throughout physiological condition doubles the incidence of harelip. different teratogens, corresponding to alcohol, anticonvulsants, and retinoic acid, area unit related to malformation patterns that embody cleft lip and surface, however haven't been directly regarding isolated clefts. Genetic abnormalities may result in syndromes that embody clefts of the first or secondary palates among the organic process fields affected. quite four-hundredth of isolated cleft palates area unit a part of malformation syndromes, compared to below 15 August 1945 of harelip and surface cases.(13) The foremost common syndrome related to harelip and surface is van der Woude syndrome with or while not lower lip pits or blind sinuses. Microdeletions of body 22q leading to velocardiofacial, DiGeorge, or conotruncal anomaly syndromes area unit the foremost common diagnoses related to isolated congenital anomaly. though there's a recognized genetic part to nonsyndromic cleft lip and/or surface, it seems to be complex. Among different recent studies, a meta-analysis of thirteen order scans by Marazita et al. (2004) unconcealed multiple cleft lip/palate genes on sixteen body regions. oldsters with a toddler with a nonsyndromic cleft, or a case history of clefting, usually raise regarding their risk of clefts in ulterior pregnancies. the danger depends on whether or not the proband features a harelip aloneOvid: Grabb and Smith's cosmetic surgery, harelip with congenital anomaly (CLP), or a congenital anomaly alone (CP). If the family has one affected kid or parent with CLP, the danger of the kid of subsequent physiological condition having CLP is four. If 2 previous youngsters have CLP, the danger will increase to Sept. 11, and if one parent and one kid were antecedently affected, the danger to youngsters of ulterior pregnancies is Revolutionary Organization 17 November. For families with a history of CP, the danger of CP to youngsters of ulterior pregnancies is 2 hundredth if one antecedently affected kid, I Chronicles if 2 youngsters were antecedently affected, 6 June 1944 if one parent has CP, and 15 August 1945 if one parent and one previous kid have CP.(14)

In most cases, the reason for cleft lip and congenital anomaly is unknown. These conditions can not be prevented. Most scientists believe clefts area unit because of a mix of genetic and environmental factors. There seems to be a bigger likelihood of clefting during a newborn if a relative, parent, or relative has had the matter. Another potential cause could also be regarding a drugs a mother could have taken throughout her physiological condition. Some medication could cause harelip and congenital anomaly.(15) Among them: anti-seizure/anticonvulsant medications, disease of the skin medications containing Accutane, and antimetabolite, a drug unremarkably used for treating cancer, arthritis, and skin disorder.

cleftlip and congenital anomaly may additionally occur as a results of exposure to viruses or chemicals whereas the craniate is developing in uterus

Symptoms of Cleft Lip and Palate

Usually, a cleft — or split — within the lip or surface is instantly recognisable at birth. birth defect and {cleft surface|birthdefect|congenitalanomaly|congenitaldefect|congenitaldisorder|congenital abnormality} could seem as a split within the lip and roof of the mouth (palate) will|whichwill|that may} have an effect on one or each side of the face and a split within the lip which will seem as solely alittle notch within the lip or can extend from the lip through the higher gum and palate into the lowest of the nose then a split within the roof of the mouth (palate) that does not have an effect on the looks of the face. Less unremarkably, a cleft happens solely within the muscles of the palate (submucous cleft palate), that square measure at the rear of the mouth and lined by the mouth's lining. this kind of cleft typically goes forgotten at birth and will not be diagnosed till later once signs develop. Signs and symptoms of submucous congenital disorder could also be issue swallowing and nasal speaking voice and continual ear infections. (16)

Historical Perspective of Combined Presurgical and Surgical Treatments

Surgeons have long recognized the challenge of the bilateral cleft deformity. The most obstacles to the repair square measure the protrusive premaxilla and therefore the deficient columella. throughout the sixteenth, 17th, and eighteenth centuries, the surgical operation concerned excision of the premaxilla followed by a surgical union of the prolabium to the lateral lip segments. At a later age, prosthetic replacement of the anterior dentition was counseled to boost facial look. within the nineteenth century, surgeons finally accepted that excision of the premaxilla removed the higher incisors and underprivileged the lip of bony support, inflicting midface deficiency, jaw constriction, malocclusions, and a visible articulator prognathism.(17) The main focus became preservation and retraction of the premaxilla to attain best lip repair. 2 treatment philosophies evolved: surgical correction alone and surgical correction following presurgical orthopaedics.

Surgical Correction

Surgical choices for premaxillary retraction enclosed fracture of the bone, surgery of a part of the bone or septum, partial surgery of the anterior portion of the premaxilla, and a full-

thickness vertical incision of the septum, that allowed the proximal and distal segments to slip over one another. though these techniques achieved the first goal of retracting the premaxilla, they were related to important complications. each long-run clinical observations and animal studies incontestible that surgery of the septum made severe growth arrest of adjacent bones. The technique had alternative limitations, together with lingual inclination of higher incisors caused by a linguistically displaced premaxilla, nasal airway obstruction, and flat facies. Another surgical approach that tried to attain premaxillary retraction and lateral phase approximation was lip adhesion, that continues to be used at some centers. Johanson and Ohlsson (1961) delineated the employment of lip adhesion before primary bone attachment. (18)Millardrumored the employment of lip adhesion within the higher third of the congenital anomaly segments in preparation for the rotation-advancement technique of ultimate lip closure. Randall (1965), victimization short, broad, triangular flaps, claimed that closure of the soft tissues formed the underlying bony structures, reduced tension within the lip, and repositioned the alar base. Randall undermined the lateral lip if necessary once there was an outsized cleft gap. The disadvantages of lip adhesion embrace the risks of an extra surgery, scarring of the concerned tissue, loss of the native membrane flaps employed in some techniques for nasal lining repair, and potential organic phenomenon of the surgical web site. additionally, the stress of the surgically adhered lip over the 26/02/13 Ovid: Grabb and Smith's cosmetic surgery ovidsp.tx.ovid.com/sp-3.8.0b/ovidweb.cgi 8/44 alveolar segments is AN uncontrolled force that doesn't invariably align the segments in a perfect position, often inflicting collapse of the dental arches. Lip adhesion ought to be restricted to those cases within which the jaw segments ar swollen while not collapse. If the segments ar medially folded, lip adhesion is of no use and a way that gives alveolar growth is preferred.

several plastic surgeons were drawn to their surgical specialty when seeing their initial congenital anomaly repair. Cleft care stands out as a rare chance in cosmetic surgery to own an enormous impact on AN infant's future psychosocial well-being, and to follow these youngsters over the youth of their lives. The doc is reminded of the success, still as of the failure, of the surgeon's primary operations for years to return. trendy cleft surgical techniques, surgical orthodontia, and specialised multidisciplinary team care modify America to attain systematically favorable primary surgical results. Repair of secondary nasal deformities, however, remains a challenge, and continues to be best treated by preventative surgery at the time of the first repair.(19) Recent “inductive” techniques, admire nasoalveolarmolding and distraction osteogenesis, have improved cleft care over the past

decade, and as comparable advances in cosmetic surgery occur within the future, a toddler born with a cleft will forestall to fewer operations with higher aesthetic and useful results.

Timing of Surgery

The optimum temporal arrangement of congenital anomaly repair balances the good thing about traditional velopharyngeal operate to optimize speech development against the potential disadvantage of impaired facial growth secondary to early surgical trauma. Graber's description within the late Nineteen Forties of restricted jaw growth following early roof of the mouth closure was in the course of a recommendation to delay surgery till four to six years old-time. due to the harmful implications of this recommendation on speech development, the standard temporal arrangement for congenital anomaly repair was at random set at eighteen to twenty four months as a compromise between speech and facial growth. the present agreement, supported an accumulated understanding of speech development, is that congenital anomaly repair ought to be completed before eighteen months of age; but, there's no general agreement relating to however early the surgery may be performed. Since Graber's earlier work, there are variety of studies supporting the idea that impaired jaw growth in cleft patients is freelance of congenital anomaly repair, and might result from the lip repair alone or is additional a results of intrinsic restriction instead of early surgical trauma. Results from previous retrospective studies examining the impact of temporal arrangement of congenital anomaly repair on speech development area unit inconsistent and area unit compromised by little study numbers and potentialy unsupportive variables. Kirschner recently retrospectively reviewed Randall's and LaRossa's cases at Children's Hospital of city, exploitation 2 relativelly solid cohorts undergoing mouth repair either before or when seven months old-time, and located no vital good thing about early closure over later repair with regard to speech outcome. These authors emphasised the one factor that the surgical community agrees on: that long well-designed prospective studies area unit needed before the optimum temporal arrangement of congenital anomaly repair may be determined.(20) There area unit presently 2 common approaches to the temporal arrangement of congenital anomaly repair in North America: (a) two-stage repair, with the mouth repair and veloplasty performed at the time of lip adhesion or primary lip repair, and therefore the surface repaired before eighteen months, or delayed any with the utilization of Associate in Nursing prosthesis, and (b) single-stage repair round the age of eleven to twelve months. Our 2 centers apply the latter approach, delaying the surgery till the time once the kid starts to demonstrate the introduction of plosives (b, d, and g) in their speech. it's at now that they

need an intact velopharyngeal sphincter muscle to continue with traditional speech mechanics. In kids with airway problems, equivalent to that related to micrognathia of capital of South Dakota Robin sequence, the surgery may be delayed till age fourteen to eighteen months to permit any lower jawbone growth and to decrease the prospect of surgical airway compromise.

Conclusion

Because clefting causes very obvious physical changes, a congenital abnormality or birth defect is simple to diagnose. prenatal ultrasound will generally confirm if a cleft exists in AN unborn kid. If the clefting has not been detected in an ultrasound before the baby's birth, a physical examination of the mouth, nose, and surface confirms the presence of congenital abnormality or birth defect once a child's birth. generally diagnostic testing is also conducted to see or rule out the presence of alternative abnormalities. easy surgery is finished to treat cleft and surface once birth.

Abstract

H. pylori is a bacterial pathogen infecting the gastric antrum of half the population worldwide. It is found to be as the major cause of gastro duodenal pathologies, including gastric and duodenal ulcers, gastric cancer and gastric B cell lymphoma of mucosa associated lymphoid tissue. Although *H. Pylori* is disappearing worldwide, infection with *H. Pylori* remains one of the most common bacterial infections in all areas of the world infecting over 50% of the human race. This article describes about the relation of *Helicobacter pylori* with ulcers, gastritis and other upper abdominal infections and focuses on many aspects of the infection that are relevant to the clinician.

Key Words: *H. Pylori, Ulcers, Gastritis, Inflammation, Triple Therapy.*

Introduction

Dyspepsia refers to a constellation of upper gastrointestinal symptoms that occur mainly in adults and is one of the most common reasons for referral to any gastrointestinal unit. It has been known for a long period of time, that bacteria are present in the human stomach. These bacteria were thought to be contaminants from digested food rather than true gastric colonizers. Barry Marshall and Robin Warren described the successful isolation and culture of a spiral bacterial species, known as *Helicobacterpylori*, from the human stomach. The discovery of gastric microbiota and the first successful culture of *Helicobacter pylori* by Marshall and Warren opened a new chapter in human medicine (1). *Helicobacter pylori* is a small, curved, highly motile, gram negative bacillus that colonises only the mucus layer of the human stomach. Since the discovery of this bacteria in 1984, it has been recognised as the principal cause of peptic ulcer disease and as the main risk factor for the development of gastric cancer. The role of *H. pylori* infection in gastric cancers is increasingly recognized, and its role in other diseases of the upper gastrointestinal tract is being evaluated. Enormous progress has been achieved in determining the pathogenesis of this infection. Effective antimicrobial therapy is available, and indications for therapy continue to evolve. This review surveys scientific knowledge concerning *H. pylori* and focuses on the many aspects of the infection caused by this bacteria that are relevant to the clinician.

Morphology

Helicobacter pylori is a helix shaped, gram negative bacterium about 3 micrometres long with a diameter of about 0.5 micrometres. It is microphillic in nature; that is, it requires oxygen, but at lower concentration than found in the atmosphere. It contains hydrogenase which can be used to obtain energy by oxidizing molecular hydrogen produced by intestinal bacteria (2). It produces oxidase, catalase and urease. This bacteria has the ability to convert from spiral to a possibly non culturable coccoid form. (3) Like any other gram negative bacteria, the outer membrane of*H. pylori* consists of phospholipids and lipopolysaccharides. The organism has 2 to 6 unipolar, sheathed flagella of approximately 3 micrometre in length, which often carry a distinctive bulb at the end. The flagella confer motility and allow rapid movement in viscous solutions such as the mucus layer overlying the gastric epithelial cells (4). In contrast to many other pathogens of the gastrointestinal tract, it lacks fimbrialadhesins.

Cultivation

A key feature of *H. pylori* is its microaerophilicity, with optimal growth at oxygen levels of 2 to 5% and the additional need of 5 to 10% CO2 and high humidity. There is no need for hydrogen, although it is not detrimental to growth. Many laboratories utilize standard microaerobic conditions of 85% nitrogen, 10% carbon dioxide, and 5% oxygen for *H. pylori* culture. Growth occurs at 34 to 40°C, with an optimum of 37°C. Although its natural habitat is the acidic gastric mucosa, *H. pylori* is considered to be a neutralophile. The bacterium will survive brief exposure to pHs of 4.

But, the growth occurs only at the relative pH range of 5.5 to 8.0, with optimal growth at neutral pH (5). *H. pylori* is a fastidious microorganism and hence, it requires complex growth media. Often these growth media are supplemented with blood or serum. They may act as additional sources of nutrients and possibly also protect against the toxic effects of long-chain fatty acids. The most commonly used solid media for routine isolation and culture of *H. pylori* consist of Columbia or brucella agar supplemented with either lysed horse or sheep blood. For primary isolation and also for routine culture, selective antibiotic mixtures are available. Growth of *H. pylori* in chemically defined media has been reported (6), but these are not suitable for routine growth and isolation of *H. pylori*. Most of the commercially available synthetic media, such as tissue culture media, do not support the growth of *H. pylori* without the addition of serum. Isolation of *H. pylori* from gastric biopsy samples is difficult and not always successful.

Epidemiology

H pylori is one of the commonest bacterial pathogens in humans. The prevalence of infection varies but has less incidence in most developed countries. Seropositivity increases with age and low socioeconomic status. Retrospective studies have shown a cohort effect consistent with the hypothesis that infection is mainly acquired in early childhood. Until recently, however, it has been difficult to assess accurately the incidence or route of infection because of the inaccuracy and cost of detecting (non- invasively)*H pylori* in young children. Primary acquisition of the infection in adults and also secondary infection after successful eradication, does occur, but is less common. Sources regarding the mechanism by which, *H pylori* is usually acquired and its route of transmission are less. Since humans are the only known reservoir of infection, it is likely that, *H pylori* may also be picked up from siblings, other

children, or parents, predominantly through the gastro- oral route.*H pylori* infection is an occupational hazard for gastroenterologists and is associated with performing endoscopy (7).

Pathogenesis

The gastric mucosa is well protected against bacterial infections. *H. pylori* is highly adapted to this ecologic setting, with a unique array of features that permit entry into the mucus, swimming and spatial orientation in the mucus, attachment to epithelial cells, evasion of the immune response, and, as a result, persistent colonization and transmission. The *H. pylori* genome (1.65 million bp) codes for about 1500 proteins. (8,9) Among the most remarkable findings of two *H. pylori* genome-sequencing projects were the discovery of a large family of 32 related outer membrane proteins that includes most known *H. pylori* adhesins. The genome of *H. pylori* changes continuously during chronic colonization of an individual host by importing small pieces of foreign DNA from other *H. pylori* strains during persistent or transient mixed infections. (10, 11) After being ingested, the bacteria have to evade the enter the mucous layer. Urease production and motility are essential for this first step of infection. Urease hydrolyzes urea into carbon dioxide and ammonia, thereby permitting *H. pylori* to survive in an acidic environment. (12) Motility is essential for colonization, and *H. pylori* flagella have adapted to the gastric environment. *H. pylori* can bind tightly to epithelial cells by multiple bacterial surface components. The best-characterized adhesin, BabA, is a 78-kD outer-membrane protein that binds to the fucosylated Lewis B blood group antigen. (13) Accumulating evidence in animal models suggests that adhesion, particularly by BabA, is relevant in *H. pylori* associated disease (14) and may influence disease severity. The majority of *H. pylori* strains express the 95-kD vacuolatingcytotoxinVacA, a secreted exotoxin. (15) The toxin inserts itself into the epithelial-cell membrane and forms a hexameric anion-selective, voltage dependent channel through which bicarbonate and organic anions can be released. (16) VacA is also targeted to the mitochondrial membrane, where it causes release of cytochrome *c* and induces apoptosis. (17) Most strains of *H. pylori* possess the *cag* pathogenicity island (*cag*-PAI), a 37-kb genomic fragment containing 29 genes. (18) Several of these encode components of a predicted type IV secretion apparatus that translocates the 120-kD protein CagA into the host cell. (19) After entering the epithelial cell, CagA is phosphorylated and binds to SHP-2 tyrosine phosphatase, leading to a growth factor–like cellular response and cytokine production by the host cell. In order to avoid the acidic environment of the lumen of the stomach, *H. pylori* uses its flagella to burrow into the mucus

lining of the stomach to reach the epithelial cells lying underneath, where there is a more neutral pH (20). *H. pylori* is able to sense the pH variants in the mucus lining and move towards less acidic region. Hence, *H. Pylori* can perform chemotaxis. This also prevents the bacteria from being swept away into the lumen, as it is constantly moving from its site of origin at the epithelium to its dissolution at the lumen interface. In addition, *H. pylori* also neutralizes the acid in its environment. It does this by producing large amounts of urease, which breaks down the urea present in the stomach to carbon dioxide and ammonia, resulting in neutralisation of stomach acid.

Inflammation, GastritisandUlcers

H. pylori harms the stomach and duodenal linings by various mechanisms. The ammonia produced to regulate pH levels is toxic to epithelial cells. Similarly, biochemicals produced by *H. pylori* such as proteases, vacuolatingcytotoxin A (VacA) and certain phospholipases are also harmful (21). Cytotoxin associated gene [CagA] can also cause inflammation and is potentially a carcinogen (22). Colonization of the stomach by *H. pylori* can result in chronic gastritis, an inflammation of the stomach lining, at the site of infection. Chronic gastritis is likely to underlie *H. pylori*-related diseases (23). Ulcers in the stomach and duodenum result when the consequences of inflammation allow stomach acid and the digestive enzyme pepsin to overwhelm the mechanisms that protect the stomach and duodenal mucous membranes. The location of colonization of *H. pylori*, which affects the location of the ulcer, depends on the acidity of the stomach (24). In people producing huge amounts of acid, *H. pylori* colonizes near the pyloric antrum to avoid the acid-secreting parietal cells at the fundus (25). In people producing normal or reduced amounts of acid, *H. pylori* colonises the remaining area of the stomach. The inflammatory response caused by the bacteria colonising near the pyloric antrum induces G cells present there to secrete the hormone gastrin, which travels through the bloodstream to parietal cells in the fundus (26). Gastrin stimulates the parietal cells to secrete more acid into the stomach lumen, and also increases the number of parietal cells. The increased acid content damages the duodenum, which may eventually result in ulcer in the area of the duodenum.

GastricCarcinoma

Two related mechanisms by which *H. pylori* could promote cancer are under investigation. One mechanism involves the enhanced production of free radicals and an increased rate of host cell mutation. The other mechanism is known as perigenetic pathway (27), and involves enhancement of the transformed host cell phenotype by means of alterations in cell proteins, such as adhesion proteins. *H. pylori* has been proposed to induce inflammation at locally high levels of TNF-α and interleukin 6 (IL-6). According to the proposed perigenetic mechanism, inflammation associated signalling molecules, such as TNF-α and interleukin 6, can alter gastric epithelial cell adhesion and lead to the dispersion and migration of mutated epithelial cells without the need for additional mutations in tumor suppressor genes, such as genes that code for cell adhesion proteins (28).

Diagnosis

Various tests have been developed for the detection of *H. pylori*, and each one have their specific advantages and disadvantages. The available tests to detect *H. pylori infection* are divided into invasive tests, based on gastric specimens for histology, culture, or other methods, and noninvasive tests, based on peripheralsamples, such as blood, breath samples, stools, urine, or salivafor detection of antibodies, bacterial antigens, or urease activity.The choice of a specific test for an individual patient dependson local experience and the clinical setting. In research protocols, a combination of two methods is often applied. In daily clinicalpractice, use of a single test is generally adequate, and mosttests are sufficiently accurate to be used for this purpose. Forroutine diagnostic purposes, histology, urea breath testing, andculture are currently most often used. In hospital-based care, many patients undergo endoscopy, which is then combined with an invasive test for *H.pylori*. Otherwise, breath tests and serology are commonly used. For children, fecal antigen tests offer the opportunity to assess *H. pylori* status without the need for endoscopy. (29)

Invasive Tests

H. pylori can be detected by endoscopy, histology, culture, or urease tests. All these biopsy based methods for detecting *H pylori* are liable to sampling error. After partially effective eradication treatment, low levels of infection can easily be missed by endoscopic biopsy. Proton pump inhibitors may affect the pattern of *H. pylori* colonization in the stomach and compromise the accuracy of antral biopsy. Hence, multiple biopsies are taken from different

sites in the antrum for histology and for one other method, either culture or urease testing. (29)

Histology

Although *H pylori* may be recognised on sections stained with haematoxylin and eosin alone, supplementary stains such as Giemsa, Genta, Gimenez,Warthin- Starry silver, Creosyl violet are needed to detect low levels of infection and to show the characteristic morphology of *H pylori*. An important advantage of histology is that, sections from biopsies can be examined at any time, in addition to the historical record provided. Biopsy specimens from other parts of the stomach can be retained in formalin to be processed only if antral histology is inconclusive. (29)

Culture

Microbiological isolation and growth of the species is the theoretical gold standard test for identifying any bacterial infection, but culture of *H pylori* can be unreliable. Risks of overgrowth or contamination make it the least sensitive method of detection, and it is the least available test for use with endoscopy. The prevalence of multi resistant strains makes it increasing likely that culture and antibiotic sensitivity testing may become a prerequisite for patients with persistent infection after initial or repeated treatment failure. (29)

Urease tests

They are quick and simple tests for detecting *H pylori* infection but indicate only the presence or absence of infection. However, the sensitivity of urease tests is often higher than that of other biopsy based methods because the entire biopsy specimen is placed in the media, hence the additional sampling or processing error associated can be avoided with histology or culture. (29)

Non-Invasive Tests

Serology

H pylori infection can elicit a local mucosal and a systemic antibody response. Circulating IgG antibodies to *H pylori* can be detected by enzyme linked immuno sorbent assay (ELISA) or latex agglutination tests. These tests are generally simple, reproducible, and can be done on stored samples. Individuals may differ considerably in their antibody responses to *H pylori*

antigens, and no single antigen is recognised by sera from all subjects. The accuracy of serological tests therefore depends on the antigens used in the test. Antibody titres fall only slowly after successful eradication, so serology cannot be used to determine *H pylori* eradication or to measure secondary infection rates. An important advantage of serological methods over other testing methods for *H. pylori* infection has been the development of simple finger prick tests, to detect the presence of *H. pylori* immunoglobulins. (30)

Urea Breath Test

Non- invasive detection of*H. pylori* by the 13C- urea breath test isbased on the principle that a solution of urea labelled withcarbon- 13 will be rapidly hydrolysed by the urease enzyme of*H pylori*. The resulting carbon dioxide is absorbed across the gastricmucosa and hence, through the systemic circulation, excreted ascarbon dioxide in the expired breath. The 13C- urea breath test detectscurrent infection and is not radioactive. It can be used as ascreening test for *H pylori*, to assess eradication and to detectinfection in children. (31)

FaecalAntigen Test

In the stool antigen test a simple sandwich ELISA is used todetect the presence of *H pylori* antigens shed in the faeces.This test have sensitivities and specificities similar tothose of the 13C- urea breath test, and the technique hasthe potential to be developed as a near patient test. (31)

Treatment

Once *H. pylori* is detected in a person with a peptic ulcer after undergoing various test methods mentioned above, the normal procedure is to eradicate the infection and allow the ulcer to heal. The eradication of *H. pylori* is strongly recommended in all patients with peptic ulcer, including those with complications.It is advised that *H. pylori* eradication is considered to be an appropriate option in patients,with functional dyspepsia, as it leads to long term symptom improvement in a subset of patients. There was consensus that the eradication of H. pylori is not associated with the development of gastro-oesophageal reflux disease in most cases, and does not exacerbate existing gastro-oesophageal reflux disease. It was agreed that the eradication of *H. pylori* prior to the use of non-steroidal anti-inflammatory drugs reduces the incidence of peptic ulcer, but does not enhance the healing o gastric or duodenal ulcer in

patients. Treatment for *H. pylori* infection should be considered with first and second line eradication therapies together. First line therapy also known as triple therapy, is done using a proton pump inhibitor or ranitidine bismuth citrate, combined with clarithromycin and amoxicillin or metronidazole. Second line therapy should use quadruple therapy with a proton pump inhibitor, bismuth, metronidazole and tetracycline. Where bismuth is not available, second-line therapy should be with proton pump inhibitor-based triple therapy. (32)

Conclusion

H. pylori continues to be one of the most common bacterial infections in humans. Functional genomics may fill many of the gaps in our understanding of the pathogenesis of *H. pylori* infection and accelerate the development of novel therapies. Associations between bacterial characteristics and disease risks have not yet been defined sufficiently well to guide the clinician in treatment decisions. Prophylactic and therapeutic vaccination have been successful in animal models, but the translation to a human vaccine remains difficult. All of these developments will probably be needed to prevent and treat this infection in areas of the world where there is a high prevalence of chronic infection of *H. pylori.* Early diagnosis and eradication of *H. Pylori* not only improves symptoms but also help to prevent complications associated with *H. Pylori* infections.

Abstract

The variety of wound types has resulted in a wide range of wound dressings with new products frequently introduced to target different aspects of the wound healing process. The ideal dressing should achieve rapid healing at reasonable cost with minimal inconvenience to the patient. Coagulation involves the regulated sequence of proteolytic activation of a series of zymogens to achieve appropriate and timely haemostasis in an injured vessel, in an environment that overwhelmingly favours an anticoagulant state. In the non-pathological state, the inciting event involves exposure of circulating factor VII/VIIA to extravascularly expressed tissue factor, which brings into motion the series of steps which results in amplification of the initial stimulus, culminating in the conversion of fibrinogen to fibrin and clot formation.Excessive surgical bleeding causes hypovolaemia, hemodynamic instability, anaemia and reduced oxygen delivery to tissues, with a subsequent increase in postoperative morbidity and mortality. The role of anaesthetists in managing surgical blood loss has increased greatly in the last decade.

Key Words: *Anticoagulants, Blood, Haemostasis, Factor VIIa, Wound healing.*

Introduction

Wound dressings and agentsplay an important role in medical and pharmaceutical wound care worldwide. In the past, traditional dressings like natural or synthetic bandages, cotton wool, lint and gauzes all with varying degrees of absorbency were used for the management of wounds. Improper clotting may occur as result of defects in blood components such as platelets and/or clotting proteins, also called clotting factors [1-5].

Their primary function is to keep the wound dry allowing evaporation of wound exudates and preventing the entry of harmful bacteria into the wound. It has now been shown however, that having a warm moist wound environment achieves more rapid and successful wound healing. Effective wound healing depends on the number of different factors such as the type of wound being treated, the healing process, patient conditions in terms of health , environment and social setting, and the physical chemical properties of the available dressings.

Skilful surgery combined with blood saving methods and careful management of blood coagulation will all help reduce unnecessary blood loss and transfusion requirements. Excessive surgical bleeding causes hypovolaemia, hemodynamic instability, anaemia and reduced oxygen delivery to tissues with a subsequent increase in postoperative morbidity and mortality [1]. Dialysis membranes and lines are inherently pro-coagulant and activate both the intrinsic and extrinsic pathways of coagulation, as well as platelets and other circulating cellular elements. To provide safe and effective dialysis, appropriate anticoagulant measures must be applied. Haemodialysis, including anticoagulation, is prescribed by dialysis doctors but delivered by dialysis nurses [2]. The agents commonly used in clinical practice for anticoagulation during haemodialysis are unfractionated heparin (UF heparin) and low-molecular-weight heparin (LMWH). When bleeding is the consequence of a specific defect of haemostasis the goal of treatment is to correct the defect. A typical example is the replacement of factor viii by transfusion in patients with haemophilia. Specific treatment may be impossible. However, because bleeding may result from multiple defects or because no cause can be identified. In such situations non-transfusion drugs that help to stop bleeding are indicated [3, 4]. These drugs may also be indicated for patients to refuse blood transfusion or for those who undergo surgical procedures associated with large blood losses necessitating many transfusions of donated blood.

Coagulation Cascade

After injury to a vessel wall, tissue factor is exposed on the surface of the damaged endothelium. The interaction of tissue factor with plasma factor vii activates the coagulation cascade, producing thrombin by stepwise activation of a series of proenzymes (thrombin generation.). Thrombin is central in the clotting process: it converts soluble fibrinogen to fibrin; activates factors v, viii, and xi, which generates more thrombin; and stimulates platelets. The normal state of the circulatory system is that of a series of conduits through which blood flows in a liquid phase, until vascular injury occurs [5, 6]. At which time it is appropriate for haemostasis to temporarily seal the defect. In the process of resolution of the vascular injury, dissolution of the haemostatic plug should also concurrently take place. The different mechanisms involved are that of a system which is overwhelmingly tipped in favour of an anticoagulant state, and except in some pathological circumstances, only with appropriate stimulation is haemostasis able to occur [7]. The mechanisms in favour of blood flowing in a liquid phase include the following:

(I) The flow of blood itself diluting any activated or prothrombotic factors;

(II) The normal laminar flow of blood through normal vasculature which prevents platelets from directly contacting the endothelium by way of a thin layer of plasma;

(III) The expression of endothelial anti-platelet and anticoagulant factors in excess of procoagulant factors;

(IV) The need for adequate stimulation to produce activated platelets, requiring multiple stimuli for full activation;

(V) The state of the circulating coagulation factors as a series of inactive zymogens, with some factors also bound to other cells or inactivating complexes, requiring receptor-mediated proteolysis for activation; and

(VI) The multiple circulating proteases which serve to degrade any rogue factors that are activated in the presence of a sub maximal stimulus.

Wound Healing

The first stage of wound management should be a thorough assessment of the wound and the patient. The process begins with a diagnosis of the wound's aetiology and continues with optimizing the patient's medical condition, particularly blood flow to the wound area. Woundhealing is a specific biological process related to the general phenomenon of growth and tissue regeneration [6].This article relates to wound management and the choice of wound dressings. It is referred to the biological and physiological texts and literature for detailed scientific expositions [8]. Wound healing progresses through a series of interdependent and overlapping stages in which a variety of cellular and matrix components act together to re establish the integrity of damaged tissue and replacement of lost tissue[9][10]. Wound healing process has been reviewed and described by 'Schultz [8] as comprising five overlapping stages that involve complex biochemical and cellular processes. Thomashas described wound exudates as: 'a generic term given to liquid produced from chronic wounds, fistulae or other more acute injuries once haemostasis has been achieved'[11]. In certain conditions that include chronic wounds, there is excessive amount of exudates present which can lead to complications. Excess exudates results from oedema caused by inflammation, reduced mobility and venous or lymphatic insufficiency [12]. Increased exudates levels may also be the result of liquefying hard and Escher-like necrotic tissue to produce a wet and sloughy mass by a process known as autolysis debridement.

The migration phase involves the movement of epithelial cells and fibroblasts to the injured area to replace damaged and lost tissue. These cells regenerate from the margins, rapidly growing over the wound under the dried scab (clot) accompanied by epithelial thickening [13].

The proliferative phase occurs almost simultaneously or just after the migration phase (Day 3 onwards) and basal cell proliferation, which lasts for between 2 and 3 days. Granulation tissue is formed by the in-growth of capillaries and lymphatic vessels into the wound and collagen is synthesised by fibroblasts giving the skin strength and form. By the fifth day, maximum formation of blood vessels and granulation tissue[3, 4].

This phase known as remodelling phase involves the formation of cellular connective tissue and strengthening of the new epithelium which determines the nature of the final scar. Cellular granular tissue is changed to an acellular mass from several months up to about 2 years [13].

Haemostasis

Bleeding usually occurs when the skin is injured and serves to flush out bacteria and/or antigens from the wound. In addition, bleeding activates haemostasis which is initiated by exudates components such as clotting factors [12]. The currently accepted model of in vivo coagulation highlights the central importance of tissue factor as the main instigator of coagulation, while emphasising the rapid amplification of thrombin as an essential step in the development of a stable clot[14], and the interdependence of coagulation factors and cellular elements. Thrombin is obtained from bovine plasma. Thrombin therapy is restricted to local application in oozing of blood[15]. Haemostasis depends on a successful balance between the coagulation, complement and fibrinolytic pathways, with complex interactions between plasma proteins, platelets, blood flow and viscosity, and the endothelium. Formation of the primary haemostatic plug at the site of a damaged vessel is the first event in the control of bleeding. Von willebrand factor binds to the exposed subendothelium, exposing multiple intrinsic binding sites for a specific platelet membrane structure termed GPIB. This is followed by platelet activation, adhesion and generation of a platelet plug [16, 17].

Haemodialysis and Clotting

Haemodialysis involves the circulation of whole blood through a dialysis circuit and artificial kidney (dialyser) both of which have the tendency to activate coagulation pathways. Bleeding usually occurs when the skin is injured and serves to flush out bacteria and/or antigens from the wound. In addition, bleeding activates haemostasis which is initiated by exudates components such as clotting factors [18]. Fibrinogen in the exudates elicits the clotting mechanism resulting in coagulation of the exudates. The dialyser is generally constructed of synthetic microfibers with narrow lumen, lacking endothelial lining and experiencing disordered flow – including both shear and turbulence. Factors that determine the thrombogenicity of different dialysis membranes include chemical composition, charge, ability to adhere or activate circulating cellular elements (including platelets) and other

characteristics which activate thrombotic pathways[19]. The dialysis circuit also has a synthetic composition and artificial surfaces with dead spaces, stasis, turbulence and an air interface in the venous bubble trap. Clotting in the dialysis circuit is triggered by both the extrinsic and the intrinsic pathways at the same time but to different degrees depending on the composition of the dialysis membrane and design and composition of the lines. Once the blood flow is initiated, plasma proteins deposit on the dialyser surface, and factor xii and high-molecular-weight kallikrein accumulate and act as initiating factors for contact coagulation – the intrinsic pathway [20]. Peripheral blood leucocytes and monocytes, which contact the dialyser membrane, become adherent or activated and release blebs of surface membrane rich in tissue factor – activating the extrinsic pathway[21].

Wound Dressing

Dressings are classified in a number of ways basedon their function in the wound they are classified into debridement, antibacterial, occlusive, absorbent, adherence, [22] and based on type of material employed to produce the dressing it can be hydrocolloid, alginate, collagen and the physical form of the dressing as ointment, film, foam, gel. Dressings are also further classified into primary, secondary and island dressings [23, 24].

Hydrocolloid dressings are among the most widely used dressings. The role of hydrocolloid dressings, their properties, mechanism of action and the range of wounds for which they are useful have been reviewed[25, 26]. The term ‘hydrocolloid’ describes the family of wound management products obtained from colloidal (gel forming agents) materials combined with other materials such as elastomers and adhesives. Typical gel forming agents include carboxymethylcellulose (CMC), gelatine and pectin. Hydrocolloid dressings are used for light to moderately exuding wounds such as pressure sores, minor burns and traumatic injuries[27].

Alginate dressings are produced from the calcium and sodium salts of alginic acid, a polysaccharide comprising mannuronic and guluronic acid units. Alginate dressings occur either in the form of freeze-dried porous sheets (foams) or as flexible fibres, the latter indicated for packing cavity wounds [26]. The use of alginates as dressings stems primarily from their ability to form gels upon contact with wound exudates (high absorbency). The

high absorption occurs via strong hydrophilic gel formation, which limits wound secretions and minimises bacterial contamination [27, 28].

Biological dressings are made from biomaterials that play an active part in the wound healing process and sometimes referred to as ‘bioactive dressings’. Bioactive wound healing dressings also include tissue engineered products derived from natural tissues or artificial sources [29]. These technologies usually combine polymers such as collagen, hyaluronic acid, chitosan, alginates and elastin. Biomaterials have the advantage of forming part of the natural tissue matrix, are biodegradable and some play an active part in normal wound healing and new tissue formation[30, 31].

The purpose of applying antibiotics and other antibacterial is mainly to prevent or combat infections especially for diabetic foot ulcers[32] surgical and accident wounds where the incidence of infections can be high due to reduced resistance resulting from extreme trauma. In some cases, the delivery of certain antibiotics from paraffin based ointments such as bismuth subgallate are known to take active part in the wound healing process[33, 34]. Common antibiotics incorporated into available dressings for delivery to wounds include dialkylcarbamoylchloride[35].

Whilst antibacterial agents prevent or treat infections and can aid in wound healing, they do not necessarily take an active physiological part in the wound healing process. Growth factors are involved with cell division, migration, differentiation, protein expression and enzyme production [36]. The wound healing properties of growth factors are mediated through the stimulation of angiogenesis and cellular proliferation, which affects both the production and the degradation of the extracellular matrix and also plays a role in cell inflammation and fibroblast activity [37]. Growth factors therefore affect the inflammatory, proliferation and migratory phases of wound healing [38, 39]. A variety of growth factors have been reported which participate in the process of wound healing including, epidermal growth factor (EGF), platelet derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factor (TGF-β1), insulin-like growth factor (IGF-1), human growth hormone and granulocyte-macrophage colony-stimulating factor [40].

Several factors apart from the choice of wound dressings need to be considered to ensure successful wound healing. In the case of chronic wounds, underlying factors such as disease,

drug therapy and patient circumstance must all be reviewed and addressed before a particular wound dressing is applied [41].

Debridement

It is important to remove necrotic tissue or foreign material from areas around the wound to increase the chances of wound healing and this process is known as wound debridement. Debridement of the wound area is important because the open wound bed cannot be observed and assessed effectively with necrotic tissue [42, 42]. The presence of necrotic tissue or foreign material in a wound also increases the risk of infection and sepsis and also prolongs the inflammatory phase, which inhibits wound healing. Several methods are employed for wound debridement including: surgical removal using scalpel and scissors, hydrotherapy or wound irrigation and autolytic removal by rehydration of necrotic tissue, for example using hydrogel dressings (see later), enzymatic removal using bacterial derived collagenases or preparations such as streptokinase[43,44]. The accumulation of devitalized tissue in the wound promotes bacterial colonization and impairs the body's ability to fight infection, thereby preventing complete repair of the wound. 3 The aim of debridement is to remove ischaemic and necrotic tissue, which presents potential for infection and contamination of the tissue by bacteria and foreign bodies [45].

Conclusion

Wound dressings and devices form an important segment of the medical and pharmaceutical wound care market worldwide. Wound healingis a biological process that relates to general phenomenon of growth and tissue regeneration. This review has considered many classes of wound dressings including topical pharmaceutical agents, traditional wound dressings and modern dressings such as hydrocolloids, alginates, hydrogel, polyurethane film and foam and novel biomaterials such as collagen, chitosan and hyaluronic acid used directly or as tissue engineered matrices for skin replacement. Haemodialysis involves the circulation of whole blood through a dialysis circuit and artificial kidney (dialyser) both of which have the tendency to activate coagulation pathways. Bleeding usually occurs when the skin is injured and serves to flush out bacteria and/or antigens from the wound. Any wounding damages the

tissue and affects the local environment. The host's response to wounding involves various processes of tissue healing that are triggered by tissue injury, and encompasses four continuous phases including coagulation and haemostasis, inflammation, proliferation and wound remodelling with scar tissue deposition. Correct clinical management may positively influence the wound healing course and reduce potential complications.

Abstract

The development of an optimum, predictable and effective orthodontic force system is predicated on the knowledge of mechanics, biomaterials and their interaction. The evolution of manufacturing technology and the development of new orthodontic techniques have led to the search for better quality alloys, more biologically effective for the teeth and supporting tissues. Aesthetics areaimportant and integral part of orthodontic treatment. With the advent of revolutionary aesthetics brackets, the need for the aesthetic wires became very strong.Orthodontics has achieved the status of a recognised specialty of dentistry because of a long period of craftsmanship and professional expertise. The evaluation of wire manufacturing technology and the development of new orthodontic technique have led to the search for better quality alloys, more biologically effective for the teeth and supporting tissues. Esthetics has become today an important and integral part of the orthodontic treatment. With the invention of revolutionary esthetic brackets, the need for esthetic wires became very strong. With the development of new alloys it becomes necessary how the available energy of tooth movement varies with wire composition of equal diameter. Since there is now a variety of orthodontic wire alloy from which choose the clinician is now faced with more decision in regard to wire selection. The quality and performance of treatment can be improved by the application of lower forces and achieves a wider range of movements between sessions. During orthodontic treatment, orthodontic wires are used as Fixed appliances to apply forces to the teeth. They release the energy stored upon its placement by applying forces and torque to the teeth through appliances placed on them. Therefore, an orthodontist should have adequate knowledge of the biochemical behaviour and clinical applications of orthodontic wires to design the treatment plan.

Keywords*: Arch Wires, strength, aesthetics, orthodontic treatment,patients.*

Introduction

Aesthetic arch wire is highly desirable to complement aesthetic brackets in clinical orthodontics. Despite advancements in the aesthetics of clear orthodontic brackets, the appearance of orthodontic arch wires has changed little.While increasing attention has been given to the use of aesthetically pleasing orthodontic archwires to complement clear brackets, these wires have not been routinely incorporated in treatment due to a lack of evidence-based research and practitioner familiarity, as well as concerns regarding fragmentation of the aesthetic coating and increased frictional resistance.Currently, aesthetic archwires can be separated into coated metal and transparent non-metallic. Each undergoes a distinct manufacturing process, resulting in unique challenges when used in treatment.(1)

The orthodontic profession is constantly seeking to improve and optimise the aesthetics of orthodontic wires since the introduction of aesthetic brackets. Nickel-titanium (NiTi) wires since their introduction to orthodontics have been extensively researched *in vitro* and are used as an initial levelling and aligning arch wire because of its properties of spring back and super elasticity. Aesthetic wires are usually either coated NiTi wires or composite wires of reinforced polymers. Shape memory polymers have wide application in space technology and are being used currently in medicine and industrial applications These wires have enormous potential for clinical application in orthodontics, and polyphenylene, a self-reinforced polymer composite, is close to being introduced to orthodontic practice.However, these wires are still at the experimental stage. A fibre reinforced polymer is in clinical use that is manufactured using a pultrusion process with a photo-cured resin however, these wires may be more likely to crack during bending and have been shown to deliver less consistent forces compared with alloy wires.The coated wires, which are currently available, either have an epoxy resin, polytetrafluoroethylyene, or a low reflectivity rhodium coating applied to the surface. Atomized Teflon particles are used to coat the wire using clean compressed air as a transport medium, which is then further heat treated in a chamber furnace.The rhodium coating is applied by using a plasma-immersion ion implantation technique. The coated wires are found to be routinely damaged from mastication and activation of enzymes.(2)

Recently, orthodontic treatment has become more common in adult patients, and the demand for improvement in the aesthetics quality of braces has been increasing. Many individuals regard metallic braces as unsightly when placed in the mouth. Although aesthetic brackets have brought a dramatic improvement in the appearance of appliances, metal arch-wires are still visible. This limitation in the improvement in appearance has led many manufacturers

and researchers to attempt to produce durable aesthetic arch wires. These wires have to be visually unobtrusive and at the same time perform the essential function of aligning teeth.

With increasing number of adult patients seeking orthodontic treatment, the demand for esthetic orthodontic appliances has increased dramatically, creating a need for the so-called invisible orthodontic appliances like invisalign(3) and lingual braces (4). However, esthetics of fixed labial appliances has also evolved by inclusion of ceramic brackets aesthetic ligatures and tooth colored arch wires. Attractiveness evaluation reveals that sapphire brackets with esthetic arch wires are preferred just next to clear aligner trays to complement the esthetic brackets with invisible arch wires, esthetic arch wires have rapidly evolved in the last decade.(5).

Esthetic arch wire materials are basically a composite of two materials which can be broadly classified into two major groups. The ceramic – polymer composite prototype of arch wires are solid polymeric wires typically made from glass fiber spindles embedded in a polymeric matrix which are manufactured through a process called photo-pultrusion. Goldberg (1992) first reported the fabrication of fiber reinforced composites (FRC) using Bis-GMA resin and S2 glass fibers, but these wires were brittle and susceptible for intraoral breakage. Burstone (2011) introduced a self-reinforced polymer (SRP) polyphenylene thermoplastic arch wires which showed flexibility comparable to NiTi and beta titanium arch wires at thin cross sections without experiencing stress relaxation.

Coated esthetic arch wires have a core of a metallic wire coated with either tooth-colored polymer or inorganic materials to conceal the visibility of the underlying alloy and impart an enamel like hue to the arch wire. Coating improves aesthetics, but creates a modified surface, which can affect friction, corrosive(6, 7)

Different Types of Aesthetic Wires

Optiflex Wires

Optiflex is a non metallic orthodontic arch wire and it has got unique mechanical properties with a highly aesthetic appearance made of clear optical fibre. They are composed of a Silicon dioxide core which provides the force or resilience to the wire. The silicon resin forms the middle layer which adds strength to the wire and also protects the core from moisture. The outer nylon layer makes the wire stain resistant and also prevents it from damage. These wires provide light continuous forces and are used during the initial aligning phase of orthodontic treatment. To prevent permanent deformation, sharp bends should be

avoided during ligation to brackets. They are available in round as well as rectangular cross section.(8)

Fibre Reinforced Composite Wires

Fibre reinforced composites (FRC) can change the concept, mechanics and application of fixed appliances through the use of partially polymerised fibre matrix complex that fully polymerises in the clinical setting. Its greatest clinical potential lies in the active applications where they are used as adjuncts for active tooth movement. They have the potential to replace metals in orthodontics as they have good bonding characteristics not only to the tooth but also to the appliance itself. An FRC can be bonded to another and attachments added directly. Three configurations of FRC that is available are Rope type- 2 mm wide, round strips, Can be wrapped around corners of an arch and thus is useful in cuspid-to-cuspid retainers and Unidirectional parallel configurations have best mechanical properties for bending.FRC can be bonded by direct and indirect technique with good bond strength, as polymeric matrix is the same as the bonding adhesive. The advantage of indirect technique being shorter curing time needed intra-orally. If attachments such as brackets, tubes or hooks, they can be directly bonded on the FRC.(9)

Marsenol

MARSENOL is a tooth coloured elastomeric poly tetrafluroethyl emulsion (ETE) coated nickel titanium wire. The working characteristics of these wire similar to an uncoated super elastic Nickel titanium wire.

Coated Arch Wires

Metallic arch wires coated with tooth-colored resin materials, such as synthetic fluorine-containing resin or epoxy resin composed mainly of polytetrafluoroethylyene, are currently the existing solution to this esthetic problem. The coating is applied in a depository process that plates the base wire, and its thickness is approximately 0.002 inches, as reported by manufacturers. Thus, a strong adhesion is achieved between the coating and the wire.

There are different opinions in the literature concerning esthetic coated arch wires. An evaluation of sliding properties and adherence of the coating to the arch wires revealed that the plastic coating decreased friction between arch wires and brackets.Some authors have experienced difficulties with these coated arch wires, claiming that the color tends to change

with time and that the coating splits during use in the mouth, exposing the underlying metal.However, despite these problems, these wires continue to be marketed and used in clinical practice, mainly when an esthetic alternative for a rectangular cross-sectional arch wire is necessary.(10)

Teflon Coated

Coating on archwire material has been introduced to enhance aesthetics and decrease friction. These wires are designed to be aesthetically more acceptable by the patient. They are given a plastic tooth coloured coating so that it can blend with the tooth colour and also of ceramic brackets. Normally the coating is 0.002" thick. The coating frequently used is TEFLON. Teflon coating is applied in two coats by conventional air spray or electrostatic techniques. These are available in natural tooth shades or in blue, green and purple colours as Lee White Wire (Lee pharmaceuticals).(11)

Epoxy Coated

Epoxy coated archwire is tooth coloured wire and has superior wear resistance and colour stability of 6-8 weeks.It is available in nickel titanium and stainless steel in preformed arches of different sizes such as round 0.016" to 0.022" NiTi, rectangular 0.018" x 0.024" to 0.021" x 0.027" NiTi and round 0.014" to 0.018, rectangular – 0.18" x 0.024" to 0.021" x 0.027" stainless steel. Epoxy coated archwires are available under the trade name of Filafex (American Orthodontics), have high tensile stainless steel core and durable tooth coloured plastic coating. It is available in preformed round 0.018" arches.They are aesthetically coated high performance NiTi super-elastic archwires and blends exceptionally well with ceramic or plastic brackets and doesn't stain or discolour plus they resist cracking or chipping.(12)

NitaniumTooth Toned Archwire

It is a super elastic Ni-Ti wire with special plastic and friction reducing tooth colored coatings which blends with natural dentition, ceramic, plastic and composite brackets and maintains its original colour. The disadvantage of the coated white colored wires is that they have routinely succumbed to forces of mastication and enzyme activity of oral cavity. On the other hand, the uncoated transparent wires have poor mechanical properties that they function merely as placebo. Esthetics is important to the orthodontist but function is paramount and anything less is unacceptable. It is marketed by Ortho Organizers and is available in round

0.014”, 0.016”, 0.018” and rectangular 0.016” x 0.022” sizes. These wires deliver gentle force.

Transparent Non-Metallic Arches

Within the past 20 years, significant advancements have been made to create nonmetallic arches whose properties resemble metal alloys. Flexible nonmetallic arches are typically made from glass spindles embedded in a polymeric matrix. Some examples of nonmetallic arches include fiber-reinforced polymer or newer self-reinforced polymer (SRP).These arches allow for a few millimetres of deformation and may be suitable for levelling and aligning in patients with Class I malocclusions with mild to moderate crowding. More importantly, they display the translucency and transparency ideal for ceramic brackets. Nonmetallic arches are not readily available. The most popular commercially availablenonmetallic arch is made by BioMers Products LLC.

The manufacturing process for nonmetallic arches will vary depending on the type of polymer. Fiber-reinforced composite (FRC) orthodontic arches are made through a production process referred to as hot-drawing. Drawing is a working process that uses tensile forces to stretch a workpiece. Hot-drawing FRC arches entails: melting of glass pellets, spinning the glass into elastic and flexible fiber strands, coating the fibers with a silane-coupling agent, and coagulation of the glass fibers and methacrylate within an acetone solution.

Properties of Aesthetic Wires

Optiflex Wires

It is the most aesthetic arch wire, completely stain resistant and will not stain or loose its clear look even after several weeks in mouth. Optiflex is very flexible. It has an extremely wide range of actions. When indicated it can be tied with electrometric ligatures to severely mal-aligned teeth without fear of fracturing the arch wire. Due to superior properties optiflex can be used with any bracket system. Optiflex arch wires should be tied into brackets with elastomeric ligatures. Metal ligatures should never be used since they will fracture the glass core. Optiflex is a totally esthetic non-metallic labial orthodontic arch wire designed by Dr. Talass in 1992 and manufactured by Ormco. It is made of clear optical fibre with distinctive mechanical properties with highly esthetic appearance and entirely stain resistant. It consists of 3 layers. A)silicon dioxide core which provides the force for

tooth movement. B) A silicon resin middle layer which protects the core form moisture and adds strength. C) A strain resistant nylon outer layer which prevents wire damage and further increases strength orthodontically beneficial properties of optiflex arch wires includes efficient tooth movement with light continuous force, increased flexibility producing a wide range of action thus invariably permitting its use with various bracket systems. However sharp bends in the wire should not be attempted. Metal ligatures should not be used as they can fracture the glass core. When cutting the distal ends of the wire use the mini distal end cutter, which is designed to cut all the 3 layers of Optiflex. It is used inadult patients who are aesthetically concerned. Optiflex wire canbe used for initial alignment. It produces less force for the same amount of deflection when compared with coaxial wires. The optiflexarch wires are expensive and needs to be changed every 4-6 weeks.(13)

Coated Metal Wires

Coated metal archwires are nickel-titanium or stainless steel wires treated with a polytetra-fluoroethylene (PTFE), epoxy- resin, acrylene-polymer, or less commonly palladiumcovering to impart an enamel hue. Manufacturers vary with regard to the coating material, thickness of the coating, and steps within the application process to maximise aesthetics, flake resistance, and mechanical efficiency. PTFE is a synthetic polymer consisting wholly of carbon and fluorine. Due to the strength of the carbon-fluorine bonds, PTFE is nonreactive, heat resistant, and hydrophobic. Most importantly, it has the third lowest coefficient of friction of any known solid, making it ideal for use as a nonstick coating for cookware, gears, plain bearings, or where sliding action of parts is needed. PTFE coating is applied to an orthodontic wire by thermal spraying, a process in which finely heated materials are sprayed in a molten condition onto a surface to form a coating. Thermal spraying of PTFE onto an orthodontic archwire entails surface treatment of the wire by sandblasting to support coating adhesion and “masking” or covering with tape areas that are not be treated, air-spraying atomised PTFE particles with clean compressed air to coat the wire, baking in a chamber furnace to cure the coating onto the wire, and removal of the masking tape. The PTFE layer adds a minimal thickness (.0008 to .001 inch) to the archwire.Though PTFE has an extremely low coefficient of friction, it is used primarily for aesthetic purposes. (14)

Fibre Reinforced Composite Arch Wire

Fiber reinforced composite arch wire Fiber reinforced composite arch wires are fabricated using a procedure called pultrusion. Fiber bundles are pulled through an extruder, in which they are wetted with a monomer resin. Then the monomer is cured with heat and pressure resulting in polymerization. Circular or rectangular wires are formed during curing. This may be shaped into a different morphology by further curing, a process known as beta staging. For this, the monomer should initially only be partially cured. The composite arch wires have higher kinetic coefficients of friction than stainless steel but lower coefficients than either Nickel-titanium or Beta-Titanium. At high forces and angulations abrasive wear of the composite surface at the arch wire-bracket interface was observed. It can lead to release of glass fibers within the oral cavity, which is unacceptable Advantages of fiber reinforced composite wires over conventional metal wires are excellent combination of high elastic recovery, high tensile strength, low weight, excellent formability, excellent aesthetics because of their translucency, ability to form wires of different stiffness values for the same cross-section which would facilitate the practice of constant cross-section orthodontics. Attachments can be directly bonded to these wires, which eliminate the need for soldering and welding. These wires can also be directly bonded to teeth obviating the need for brackets, in certain situations, e.g. where anchorage from a large number of teeth is required. It is a safer choice for patients with nickel allergy.

Composite arch wires had higher kinetic coefficients of friction than stainless steel but lower than nickel-Titanium or beta titanium. The composite arch wire retained sufficient resilience to function during initial stage of orthodontic treatment and also during intermediate stages of orthodontic treatment.Burstone and Kuhlberg introduced a new fiber reinforced composite called "Splint-It" which has S2 glass fibers in a bis GMA matrix. Various configurations such as rope, woven strip and unidirectional strip are available. These materials are only partly polymerized during manufacture, which makes them flexible, adaptable and easily contourable over the teeth. Later they are completely polymerized and can be bonded directly to teeth. It can also be used for various purposes such as post treatment retention, as full arches or sectional arches, and to reinforce anchorage.(15)

Fibre reinforced composites (FRC) can change the concept, mechanics and application of fixed appliances through the use of 'pre-preg' or partially polymerized Fibermatrix complex that fully polymerizes in the clinical setting. Its greatest clinical potential lies in the active applications where they are used as adjuncts for active tooth movement. They have the potential to replace metals in orthodontics as they have good bonding characteristics not only to the tooth but also to the appliance itself. An FRC can be bonded to another and attachments added directly. Fibre reinforced composite are available as three configurations such as A)Rope type- 2 mm wide, round strip. B)Can be wrapped around corners of an arch and thus is useful in cuspid-to-cuspid retainers.C)Unidirectional parallel configurations have best mechanical properties for bending.

FRC can be bonded by direct and indirect technique with good bond strength, as polymeric matrixis the same as the bonding adhesive. The advantage of indirect technique being shorter curing time needed intra-orally. If attachments such as brackets tubes or hooks, they can be directly bonded on the FRC.

Advantages of FRC

i. Esthetic as the connecting bar is clear or translucent.

ii. Biocompatible and less hypersensitivity reported as compared to stainless steel and other metals.

iii. High modulus of elasticity in flexure (70% greater than highly filled dental composite), six times greater yield strength and 2 times greater resilience.

iv. Option to join pieces together with an adhesive to make a string structural unit.

v. Attachments can be added for inter-maxillary tooth movement without bands or brackets, making it simple to position hooks with ideal direction and point of force application respective to maxillary and mandibular centre of resistance.

vi. Vertical elastics can be applied directly to FRC bars, either on full arches or on segments for closure of an open-bite.

vii. Intra-arch movements such as space closure, with bonded tubes on FRC bars, which can be positioned to increase the inter-bracket distance.

viii. Correction of poorly erupted second molars after completion of orthodontic therapy can be done by uprighting the tooth using full-arch FRC as an anchorage unit. Active force applied by straight wire segment, T-loop or wire with differential bend.

ix. Ease of modification as more layers can be added if greater rigidity required. Attachments can be repositioned, repaired or replaced any time.

x. Passive applications such as bonded tooth-to-tooth retainer can be made with ideal esthetics as compared to metal wire bonded retainers.

FRC bars are strong and rigid in tension but less in bending mode and are weakest in shear and torsion. Unlike metals, they are not homogenous materials so shear loads need to be minimized. Sound bonding technique is required.FRC is available as 'Splint-it', a commercially available long-fiber-reinforced composite, uses strong S-glass fibers. The matrix is light cured thermoset bisGMA with the fibers correctly oriented gives excellent coupling. FRCs are produced in two steps. In the first step, "Amount, distribution and wetting of fibers by resin is closely controlled" and in the second step "Composite is formed into desired final shape".

Two important processes associated with fabrication of FRCs, i.e., Pultrusion and Beta staging.

Pultrusion: It is the process of manufacturing components having continuous lengths and a constant cross sectional shape such as in arch wire. In this bundle of continuous fibers are impregnated with polymeric resinand are then pulled through a Sizing Die that performs composite and establishes resin/fibre ratio. The bundles are then passed through Curing Die which imparts precise shape as it cures the resin.

Beta Staging: It is an intervening process in which partially cured resin and its bundles of continuous fibers are deformed into another form (e.g. preformed archwire) after which the curing is completed. Preformed arch wires and rectangular cross-section is possible by this process.(16)

FRC is Tooth coloured and they vary in stiffness from that of most flaccid multi-stranded wire to nearly that of β-Ti arch wire. These characteristics can be varied during manufacture without any change in wire slot engagement by pultrusion. Mechanical tests show that such arch wires are elastic until failure occurs and when failure does occur the wire loses its

stiffness but remains intact.When compared with NiTi, resilience and spring back are comparable. Specifics of other characteristics such as formability, weldability and frictional coefficients are unknown at this time. Low coefficients of friction and enhanced biocompatibility should be possible by modifying the surface chemistry of polymer. Like the advanced metal wires, their shape is very difficult to change once the manufacturing process is completed which leads to a number of practical problems for clinical applications.(17,18)

Clinical Implications

It is used in adult patients who wish that their braces not be really visible for reasons related to personal concerns or professional consideration. It can be used as initial arch wire in cases with moderate amounts of crowding in one or both arches. It should be used in cases to be treated without bicuspid extraction. Optiflex is not an ideal archwire for major bicuspid retraction. Optiflex can be used in pre-surgical stage in cases which require orthognathic intervention as a part of the treatment.(19)

Drawbacks

Coated metal arch wires with circumferential coating deliver statistically lower loading and unloading force levels than coated wires of the same nominal sizes. The lower force levels of coated wires may be attributed to the thick aesthetic coating having a negative effect on the load- deflection properties and a manufacturer’s use of a smaller- diameter wire to compensate for the thick coating, particularly for epoxy-coated arch wires. Additionally, the fragmentation of the coating adds increased frictional resistance and diminishes the aesthetic benefit. Meanwhile, nonmetallic arches are brittle and allow for only moderate deformation. Excess deformation or forceful grip with pliers can lead to permanent deformation and irreversible cracks, referred to as “craze lines.” These clear arches are restricted with regard to torque, detailing, and changes in arch width, and they are currently not suitable for patients requiring consolidation or anteroposterior correction(20).

Conclusion

Appearance is one of the patients' main concerns during orthodontic treatment. There is a growing demand for aesthetic orthodontic appliances and by the effect of this demand; most

of the companiesproduced many new aesthetic appliances.The new aesthetic appliances provided better appearance for the patients and acceptable results for clinicians but these appliances must be studied by the researchers more and also must be developed.

Comparison of Adverse Effects of Labial and Lingual Orthodontic Treatment-AReview

T. Nandhini[1], SaravanaPandian[2], ManishRanjan[3],

Graduate Student[1],Senior Lecturer[2], Department of Orthodontics[2],Reader[3], Department of Conservative Dentistry[3],

Saveetha Dental College,Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstract

The aim of this review is to compare the adverse effects of lingual and labial orthodontics.To compare adverse effects between labial and lingual orthodontic treatments through a review of literature. Lingual orthodontic came into existence to eliminate the visibility of the appliance by sparing the labial surface and making use of lingual surface to fix the orthodontic attachments for aesthetic reasons on the demand of adults. Orthodontic treatment is often part of a comprehensive dental health care plan. With good care, including orthodontic treatment when necessary, teeth can last a lifetime. A variety of orthodontic "appliances" are available today. The purpose of this review is an attempt to present an overview of lingual orthodontic versus labial orthodontic.

Key Words*: labial orthodontic, lingual orthodontic, intrusion of anterior teeth, direct bonding, indirect bonding.*

Introduction

The goal of orthodontic treatment is a beautiful smile and a good bite meaning straight teeth that mesh well with the teeth in the opposite jaw and look great. Many people find a beautiful smile adds to self-esteem, self-confidence and leads toward career advancement. We live in a competitive world and a great smile can give you the edge.

Orthodontic treatment is often part of a comprehensive dental health care plan. With good care, including orthodontic treatment when necessary, teeth can last a lifetime. A variety of orthodontic "appliances" are available today, Options include traditional metal braces, tooth-coloured braces, braces that go behind the teeth, clear aligners and other devices, as appropriate.

Comfortable and efficient, today's orthodontic appliances also contribute to a stable, long-lasting result. While the appliances used in orthodontic treatment have come a long way since orthodontics became dentistry's first specialty in 1900, what endures is orthodontists' desire to help you achieve your healthiest bite possible.

Recent years have witness a noticeable increase in the demand for lingual orthodontic appliances among orthodontic patients looking for aesthetic improvement (1). Several seminal studies indicated that lingual appliances can afford treatment outcomes comparable to those achieved with labial appliances (2, 3). Lingual orthodontic appliances take pleasure in aesthetic advantages over conventional labial orthodontic appliances (4).Moreover, it has been claimed that lingual appliances put up with a lower risk of caries (5).Nevertheless, strong concerning the tongue soreness and difficulty in speech have arise regarding lingual orthodontic appliances (6-9).Natural products derived from plant source are found to be highly efficient in eradicating the dental caries/plaque found in fixed orthodontic appliances patients undergoing orthodontic treatment (10).

Specifically, it was recently reported by Khattab et al.(11) that more significant speech deteriorations were associated with lingual orthodontic treatment than labial appliances. However, to date, the reliability of this evidence has not been critically assessed. Therefore, a review that critically evaluates the reliability of evidence is necessary for relevant dental

practitioners. So this review is to compare adverse effects between lingual and labial orthodontic treatment.

Labial Orthodontic Treatment and Lingual Orthodontic Treatment

Fixed appliances are individuals which are fitted to the teeth and cannot be disconnected by the patient at will. A variety of complex tooth movements be finished possible with fixed appliance (12). Brackets and arch wires were located on the labial surface of the teeth for labial orthodontic treatment. Lingual braces are one of the many types of the fixed orthodontic treatment methods available. It involves attaching the orthodontic brackets on the inner sides of the teeth which is not easily visible from outside. The main advantage of lingual braces is its near invisibility compared to the standard braces which are trapped on the buccal sides of the tooth.Lingual braces were invented by Craven Kurz.

Brackets were initially bonded with a system known as Torque Angulation Referencing Guide (TARG) which allowed a clinician to place brackets on lingual surfaces of teeth by using the natural anatomy. Then another method called Custom Lingual Appliance Set-Up Service which allowed a clinician to set up brackets on a model first and then indirectly bond them on patient's teeth later on with a tray.

Lingual orthodontics began in 1970's when Fujita in Japan and Kurtz in the USA utilized lingual sections out of the blue. It made an amazing presentation as lingual sections were undetectable, and the quantity of started cases expanded exponentially. A couple of years after the fact, the quantity of lingual orthodontic cases diminished incredibly. The reason was clear; most specialists couldn't accomplish palatable outcomes with lingual orthodontics. Following this, underlying advancement and extension of lingual orthodontics in the 1990s, intrigue, especially in the United States, diminished, likely because of the poor consequences of finished cases(13).As time passed and critical thinking related with lingual orthodontics was enhanced, lingual orthodontics extended far and wide, particularly in European and Asiatic nations .

ApplianceDesign

Lingual section framework has developed from original Ormco lingual sections to PC supported plan/PC helped fabricating (CAD/CAM)- based totally modified lingual apparatus. Original Ormco lingual sections of 1970's were developed to seventh era in 1990's, the progressions were made in the profile of the section, expansion of snares, consolidation of rhomboidal shape chomp planes, and expanded mesiodistal width of the premolar sections for better rotational control.Mushroomarchwires have been being used since Fujita began lingual orthodontics which regularly requires vertical advance curves and insets amongst canine and first premolar and muddled wire twists. Scuzzo and Takemoto in 1995 presented lingual straight wire method and STb sections and showed that lingual straight wires can be utilized if the sections are repositioned gingivally since the distinction in thickness of the canines and premolars diminishes with the holding tallness. Weichmann in 2002 altered the idea of lingual orthodontics by presenting CAD/CAM-based modified lingual apparatus and automated wire twisting. In 2009, 3M Unitek assumed control over this modified apparatus and presented it as Incognito™ lingual appliance.Fillion in 2010, additionally built up a redid straight-wire procedure, utilizing the Orapix advanced framework to create lingual machines from a virtual setup. There are numerous modified lingual frameworks accessible today: WIN (DW Lingual Systems GmbH), HARMONY (American Orthodontics), and Indian tweaked lingual frameworks: Lingual Matrix and iLingual 3D. Scuzzo in 2011 presented first self-ligating lingual sections with square space (14). As indicated by their analyses, the square opening (0.018 inch × 0.018 inch) is better than rectangular space in rotational control with both round and square archwires.Kairalla in 2014 built up four lingual curve sizes: S, M, L, and XL and state of lingual curve frames was portrayed like a parabola, somewhat smoothed on its foremost area (15). Stop in 2015 additionally gave another arrangement of maxillary and mandibular lingual curve frames: Narrow, decreasing and ovoid as indicated by intercanine and intermolar widths and their best-fit bends on lingual surface of dentition(16).

Indirect Bonding and Laboratory Setup

The morphological varieties of lingual dental surfaces constrain the immediate holding of sections on lingual surface precisely and decisively. Consequently, backhanded holding procedure is essential for achievement in lingual orthodontics. There are distinctive research facility methods which have been created for aberrant situating and holding of lingual sections. Research center setup for circuitous holding of lingual apparatus can be separated into two classifications, one is manual setup which utilizes patient's dental models and

incorporates different strategies (BEST, CLASS, and HIRO, and so on.), the second is totally redone advanced lingual setup (Orapix, WIN, HARMONY, Incognito™ and Lingual Matrix, and iLingual III D,) individualized for every patient, made by utilizing patients examined model or three-dimensional (3D) picture and sections are composed and made by CAD/CAM innovation.

Disadvantages

Initial appliances formed in 1980s irritated patient's tongues and had higher breakage rate. However, different companies made the bracket profile smaller and smoother which allowed less frustration to soft tissues around the bracket. However, the same problems still persisted over the years and treatment move towards is to inform the patient that irritation and speech impairment will recover in 2–3 weeks after the bracket placement. Furthermore, initial brackets had bracket hooks which were long and caused gingival impingement. This was familiar in the later generations of brackets which had smaller hooks and did not interrupt the gingiva. Lingual braces are also related with extended chair time or an orthodontist which may or may not be beneficial for the source. Labial movement of teeth during orthodontic treatment may result in gingival recession in the upper or lower anteriors. In the absence of keratinized gingiva, orthodontic treatment only further deteriorates gingival health. In 28.6% of the cases undergoing tooth movement, gingival clefting occur (17).

Advantages

An advantage of the lingual brackets over the buccal brackets is the less decalcification marks on the buccal side of the teeth which is more visible to the naked eye. Patient's with poor oral hygiene can have increased white spot lesions which present themselves buccal and can stay there post- orthodontically if proper oral hygiene is not maintained.

Treatment Effects

Intrusion of Anterior Teeth

Lingual brackets are positioned more closer to the centre of resistance of a tooth then brackets which are placed on a buccal surface of a tooth. Thus when a patient bites down, the biting forces are focussed through the centre of resistance of those anterior teeth. As the mandibular teeth are biting on the upper brackets, it results in an anterior bite plane effect. This ultimately leads to the light, continuous intruding force that is being felt on the front

incisors. This bite plane effect may also induce slight opening in the posterior molar teeth and these teeth may extrude, leading to correction of deep bite. However, forces that are felt on]the anterior teeth seem to be minimal, in milligrams. An optimum force is essential to intrude teeth is 30-40g.

Changes in the Oral Environment after Placement of Lingual and Labial Orthodontic Appliance

The lingual orthodontic group could be explained by the fact that plaque deposit on the lingual gingival margin of the teeth are more difficult to remove with standard oral hygiene procedures with respect to the labial side; if maintained for a long time, they represent a bacterial injury for the gingiva and can cause gingival inflammation. According to many retrospective (18,19,20) and prospective studies (21,22) of the literature, wider lingual brackets cause a reduced inter bracket distance and make oral hygiene procedures very difficult with following risk for plaque accumulation and gingivitis.

In Speech

Lingual orthodontic patients are usually having some tongue discomfort and speech difficulty associated with the insertion of the appliance. However, the intensity and duration of the problems are not so far entirely clear and orthodontists are still doubtful of the patient's ability to adapt to the lingual bracket (23). Lingual appliances do cause more speech changes than the labial appliance. The insertion of fixed labial orthodontic appliances has a variable effect on speech sound production. In some patients, a transient negative change is seen. In others, a more persistent change is seen over a period of 2 months. In approximately 40%, no change is noted.Both sibilant and stopped sounds are affected by fixed labial appliance insertion. However, the sibi- lants, most notably /s/, are affected most often.The ability to accommodate sound production to the presence of fixed labial appliances, immediately and over time, depends to some extent on the severity of the malocclusion (24).

Biomechanically

Theoretically retraction forces used in the lingual technique is three-fold lower than that with labial technique. Controlling the position of anterior teeth is difficult in LiO, due to the unpredictability in the morphology of the palatal surface of the anterior teeth, the reduced

distance between the point of force application to the center of resistance of the tooth, the small inter bracket distance, influencing arch wire rigidity, and friction (25).

The sliding mechanics with lingual orthodontics also has the advantage of being effective in preventing transverse bowing effect leading to undesired buccal tipping of premolars and distolingual rotation of molar without using any auxiliary such as transpalatal arch. The lingual orthodontics shows expansive nature especially during alignment. This effect was first attributed to increase in tongue pressure as a result of placement of appliance on the lingual aspect but later it was realised to be a mechanical side effect/bowing effect, which can be controlled by use of stiff wires while retraction.

Agony

There has been a change in outlook inside orthodontics to the utilization of lingual settled machines instead of ordinary labial settled apparatuses in the treatment of malocclusions. Lingual machines can deliver an equivalent treatment result over comparative eras and are accordingly an elective treatment methodology for patients to consider. Albeit lingual machine treatment is frequently more costly than ordinary labial apparatus treatment, it has evident tasteful focal points amid the dynamic treatment stages for instance, even shading coordinated labial sections seem to offer no option in style contrasted and the lingual system .

Poor feel, be that as it may, are by all account not the only outcome of orthodontic treatment. Torment is one of the best aversions and a noteworthy dread of orthodontic treatment .

Besides, torment is a typical motivation behind why orthodontic treatment is hindered and even ended, influencing consistence and treatment times.Accordingly, it is basic that experience of agony is considered in the orthodontic treatment basic leadership process.

The experience of torment from traditional settled labial apparatuses has for some time been accounted for following the arrangement of orthodontic separators to archwire position and initiation, especially in the beginning periods of treatment. There is clashing confirmation in regards to torment experienced by those wearing removable orthodontic machines contrasted and those treated with regular labial apparatuses An ongoing report has recommended that Invisalign® causes less agony amid treatment than traditional labial machines (26). There is a

lack of data looking at the experience of agony among those treated with regular labial contrasted and those treated with lingual apparatuses.No huge contrasts in patients' worldwide evaluations of torment experienced amid treatment were seen between those treated with labial or lingual apparatuses.

Eating troubles

Ata-Ali in 2016, in their efficient audit, inferred that eating difficulties were not observed to be factually more typical with lingual than with buccal appliances(27).

White Spot Injuries

It is beneficial that lingual xed apparatuses are related with decreased rate of WSLs when contrasted with labial xed machine as detailed by different examinations including RCT and efficient surveys. A RCT led by van derVeen et al. in 2010, revealed that the quantity of new WSLs creating or advancing on sectioned buccal surfaces was 4.8 times higher than the quantity of new WSL creating or advancing on xed lingual surfaces (28).Wiechmann et al. in 2015, in their examination on totally tweaked xed lingual machine likewise discovered unmistakably diminished WSL (29).

Consideration Regarding Appliance Placement

Lingual orthodontics presents difficulty for appliance placement firstly, due to difficulty in direct accessibility to lingual surfaces and secondly, due to anatomic variations of the lingual surfaces and thereby, increasing the chances of inaccuracy of bracket positioning. Precise bracket positing is important for successful treatment. A change in bracket position on lingual side will have a greater effect on the final tooth position than the same change when applied on labial aspect because lingual brackets are bonded distally from the labial surface that has to be aligned. Precise bracket positioning is achieved either by direct bonding with lingual jigs (30), which also enables indirect bonding or by indirect bonding using TARG system(Torque Angulation Reference Guide), (31) the slot machine, the CLASS system (Customised Lingual Appliance Setup Service), the CRCS system (Convertible Resin Core System, the bending arch technique, the TOP system (Transfer Optimised Positioned). Direct bonding is less accurate, therefore indirect bonding is preffered.

Considerations Regarding Patient’s Acceptibility to the Appliance

Both labial and lingual patients feel discomfort at the beginning of the treatment and adaptation period for the patient to be comfortable with the appliance was the similar in the patients with either of the technique. Patients felt discomfort localised in lip and cheek areas with labial appliance, where as those with lingual appliance complained of tongue soreness as a common occurrence (32). No difference was observed in the eating and oral hygiene maintenance, but food sticking was also present .Speech was also found to be severely affected in patient with lingual appliance. Patient should be very cooperative and able to understand the discomfort caused by the appliance and need to be tolerant .Lingual orthodontics is associated with extended chair time in comparison to labial orthodontics. increasing in time, effort and support of a laboratory all lead to increase in the cost, which may discourage a patient from seeking lingual orthodontic treatment.

In labial orthodontics, white spots on the labial surfaces around the orthodontic attachments may be discovered after removal of appliance leading to anaesthetic appearance. In lingual orthodontics, such chances of white spot formation on labia surfaces can be eliminated by maintenance of proper oral hygiene as labial surface is spared of orthodontic attachments, this advantage is in favour of lingual orthodontics.

Considerations Regarding Selection of Appliance

The lingual appliance has a bite opening effect due to the position of lingual brackets on maxillary anterior teeth contacting incisal surfaces of lower incisors in deep bite cases as well as expansive nature. Therefore, the favourable cases are low angle, deep bite cases, mild crowding cases requiring expansion and class II cases requiring maxillary premolar extraction, high angle cases, anterior open bite cases and surgical cases. Unfavourable cases making contraindication to lingual orthodontics are cases having short clinical crowns less than 6mm, poor periodontal status, poor oral hygiene, patients having criticizing and restless tendency with a little hope of understanding the problems of discomfort, high angle cases, severe class II discrepancy and acute TMJ dysfunction (33,34).

The present confirmation on lingual orthodontics demonstrates that any case that can be treated with labial orthodontic apparatus can likewise be dealt with successfully with lingual orthodontic machine. As the quantity of grown-up patients looking for orthodontic treatment is expanding, the interest for stylish orthodontic machine is likewise expanding. Lingual

orthodontics is the main orthodontic apparatus which has preference of finish imperceptibility and 3D control of orthodontic tooth development.

Conclusion

This audit article has arrived at the accompanying conclusion,the confinements of manual setups, for example, repetitive research center strategies, error in section situating, visit debonding of sections, issue in rebonding of sections, troublesome and tedious control of the apparatus, powerlessness to express and control the torque in foremost portion successfully and poor standard of treatment result, now can be effectively tended to with the coming of totally modified lingual machine.

The main issue with the totally tweaked lingual machine today, is the cost of the machine which can be overwhelmed with the accessibility of cutting edge innovation like "metal" 3D printers which straightforwardly can make the metal sections without making the wax designs as in the ebb and flow strategy. Biomechanical standards of lingual orthodontics have been totally comprehended and set up today. The issue of torque control of front teeth can be tended to with the utilization of palatal smaller than normal screws and lever arms which influence the purpose of use of withdrawal to drive at the level of focal point of obstruction of upper foremost teeth amid as once huge mob withdrawal. Patients with lingual machines will probably report a view of enunciation change and shirking of a few sorts of discussion. The patient as a rule protestations of discourse issues identified with the lingual machine that may persevere until 1 month after beginning of the lingual treatment or even following 3 months in a few patients. There is no noteworthy contrast in torment experienced amid treatment between those treated with labial or lingual apparatuses. Ata-Ali et al., in their meta-examination, found a more prominent trade off in oral cleanliness levels with lingual machine It is favorable that lingual settled apparatuses are related with decreased rate of WSLs when contrasted with labial settled apparatus as detailed by different investigations including RCT and orderly audits. A deliberate survey has indicated empowering consequences of the clinical result related with the lingual orthodontic treatment, particularly concerning the accomplishment of individualized treatment objectives with the totally altered lingual apparatus.

Lingual appliance is a feasible option for the patients seeking fixed orthodontic treatment. It is a well – tolerated appliance. Speech problem and tongue soreness may require some more time for adaption to the appliance. Lingual technique due to poor accessibility, variations in anatomy of lingual surfaces, need of a laboratory and complicated mechanics, increased duration and cost, needs a much different consideration as compared to labial orthodontics. Hence, a good communication between the orthodontist and patient is required so that patient is able to understand the problems associated with lingual orthodontics and adopts positive attitude to accept the appliance with good cooperation.

Abstract

Root canal irrigation plays an important role in the debridement and disinfection of the root canal. The most commonly used irrigants are sodium hypochlorite and hydrogen peroxide and have good benefits of tissue dissolving and disinfection capability. Sodium hypochlorite is an effective agent against a broad spectrum of bacteria and also dissolves the necrotic tissue. However, it also produces toxic effects on the vital tissues resulting in ulcer, necrosis etc. The aim of this review is to analyze the factors causing or affecting the Root canal irrigation during a root canal treatment.

Keywords *swelling, tissue necrosis, pain, haemorrhage, echymosis*

Introduction

The main aim of a root canal treatment is to ensure complete removal of connective tissue and destruction of residual microorganisms found in the infected root canals. To allow proper debridement and disinfection of root canal systems, root canal irritants like sodium hypochlorite and hydrogen peroxide play an important role during the procedure [1]. The complexity of root canal system, presence of numerous dentinal tubules in the roots, invasion of the tubules bymicroorganisms and preservation of healthy dentin after achieving the primary objectives of complete shaping and cleaning of root canal systems are done with the help of a proper irrigation [2]. However many mishaps can occur while cleaning and shaping the root canals with irrigating solutions ranging from damage to the patient's clothing, splashing the irrigant into the patients or operators eye, to allergic reactions. Some of the most commonly used irrigants are sodium hypochlorite, chlorhexidine,ethyelenediaminetetracetic acid (EDTA) and a mixture of tetracycline, an acid and a detergent (MTAD).Hence, the ideal properties of an irrigant [3] include, a potent tissue debris solvent ,low toxicity, low surface tension, lubricant, sterilizing agent, removal of smear layer, low cost and inactive endotoxin

Endodontic Irrigants

Non-Bactericidal Irrigants

Some general dental practitioners either use saline, local anaesthetics and/or distilled water. These have no antibacterial action and will not lessen bacterial significantly. These irrigants may be used regularly as they are easy to use and readily available. In the case of local anaestheticssolutions, they also come in sterile packaging and can be distributed easily through very small gauge needles. Extra contributing factors for their use may be safety. These irrigants should have no role in handling infected root canals. There are a number of better irrigating solutions existing which are more suitable for managing infected root canals.

Bacteriostatic/Bactericidal Irrigants

These include acollection of solutions which also kill bacteria or enable their death by allowing other irrigants to come into contact with the bacteria.

Sodium Hypochlorite (NaOCl)

Sodium hypochlorite was first recognized as an antibacterial agent in 1843 and used as a hand wash with low rates of infection transmission. Its advantages are two-fold; pulpal dissolution and antimicrobial effect. There is evidence to show that a decrease in microbial numbers is achievable when using NaOCl for endodontic treatment of teeth with apical periodontitis. Itwas used as an endodontic irrigant,withlow viscosity ,effective antimicrobial properties but low tissue dissolving capabilitiesacceptable shelf life , easily available and inexpensive [4]. The mechanism of actioninvolvesbreak down of protein by dissolution of amino acid content of vital and necrotic tissue by the available free chlorine in NaOCl

However, certain disadvantages of this irrigant are the toxicity to the vital tissues. The major disadvantage include cytoxicty when injected into periradicular tissue, foul smell and foul taste, fabric bleach on accidental spillage and corrosiveon metals [5]. Studies have also shown extrusion of irrignat the patient experienced a sharp, severe pain and an increased swelling.

Hydrogen Peroxide

Hydrogen peroxide (H_2O_2) is a colorless liquid and has been used in dentistry in concentrations varying from 1% to 30% [6]. H_2O_2 degrades to form water and oxygen. It is active against viruses, bacteria, bacterial spores and yeasts via the production of hydroxyl free radicals which attack proteins and DNA [7]. It has been shown that NaOCl, combined with H_2O_2, is no more effective against E. faecalis than NaOCl alone [8], however, CHX combined with H2O2 was a better antimicrobial agent than either one on their own.

Chlorhexidine

Chlorhexidine digluconate is widely used in disinfection because of its excellent antimicrobial activity. It is highly antimicrobial especially at pH 5.5-7.0 and is known for its longlasting effectiveness even after the removal of the solution but does not provide any tissue dissolving properties [9].It is a positively charged hydrophilic and lipophilic molecule which relates with phospholipids and lipopolysaccharides in cell membranes. Consequently, there is disruption of the cell membranes which allows CHX molecules to enter the cell to cause intracellular toxic effects, such as coagulation of the cytoplasm. Other advantages include available in acceptable flavor and not injurious to the surrounding tissues. Chlorhexidine has a unique property in that it has substantively, i.e. has a persistent residual antimicrobial action.It can theoretically prevent microbial colonization for a period of time after the actual medication period. Commonly, Chlorhexidine is used in conjunction with NaOCl as an irrigant as it raises the effectiveness of the irrigation protocol [10].

However, in spite of the advantages chlorhexidine cannot be considered as an ideal root canal irrigant because of its inability to dissolve necrotic tissue remnants [11]. But capable of dissolving the smear layer [12].Additionally studies have revealed the presence of desquamategingivitis, discoloration of teeth and tongue or dysgeusia associated with it .Laboratory findings showed chlorohexidine to be highly cytotoxic to human periodontal cells, fibroblast via inhibition of protein synthesis [13]. While it does not appear to cause any long term damage to host tissues, it may still cause an inflammatory response in these tissues if expressed beyond the root canal [14].

MTAD

MTAD is a mixture of 3% doxycycline, 4.25% citric acid and detergent developed by Torabinejad et.al. The irrigant has a combination of both chelating and antibacterial properties [15]. MTAD has been reported to be effective in removing the smear layer. The citric acid may serve to remove the smear layer, allowing doxycycline to enter the dentinal tubules and exert an antibacterial effect [16]. MTAD is considered to be more superior to Cholorhexidine in antimicrobial activity and is also7more biocompatible and enhances bond strength [17]. MTAD was seen to be less toxic than eugenol, 3% H2O2, CA (OH) 2 paste, 5.25% NaOCl, Peridex (a

CHX mouthwash with additives) and EDTA, however, was more lethal than NaOCl in absorptions of 2.63%, 1.33% and 0.66%. The procedure for clinical use of MTAD is 20 minutes with 1.3% NaOCl followed by 5 minutes of MTAD and is available from DENTSPLY as Bio Pure MTAD. This irrigant is based on a tetracycline isomer; there may be problems with staining, resistance and sensitivity.

EDTA

Ethylenediaminetetraacetic acid (EDTA) is a synthetic amino acid and the sodium salts of EDTA (Na2EDTA) are used in dentistry. It is often used as a chelating agent and is non-corrosive to instruments. EDTA is not bactericidal nor bacteriostatic but inhibits the growth of, and eventually kills, bacteria by starvation as metallic ions needed for growth are chelated thus are not available for use by micro-organisms . EDTA is relatively nontoxic but is slightly irritating in weak solution. EDTA at concentrations of 15–17% removes calcium from dentine leaving a softened matrix of dentine. It also emulsifies soft tissue and removes the smear layer with no deleterious effect to pulpal or periapical tissues. EDTA reacts with the calcium ions in dentine and forms soluble calcium chelates. It is considered to be superior to saline in reducingtheintracranialmicrobial flora and also helps to detach biofilms adhering to root canal walls [18]. However irrigation with 5%NaOCl or alternated with 17% EDTA, significantly increased the tooth strain .It reduces the chlorine in solution, rendering the sodium hypochlorite irrigant ineffective on bacteria and necrotic tissue [16]. A one minute application of 17% EDTA combined with ultrasonic is efficient for smear layer and debris removal in the apical region of the root canal [19]. EDTA is available in a liquid form for irrigation and a gel form for lubrication (Glide File Prep, Dentsply-Maillefer, and Ballaigues, Switzerland). A well-known alternative is Citric Acid; however, EDTA has been shown to be a faster chelating agent.

Other Irrigating Solutions

The other irrigating solutions are sterile water, physiologic saline, iodine compounds, ureaperoxide, etidronic acid, citricacid, maleic acid, tetraclean, chlorine dioxide etc [20].

HEBP is also known as etidronic acid or etidronate and has been proposed as an alternative potential alternative to EDTA or citric acid because it shows no reactivity with NaOCl [19]. It is nontoxic and has been also used to treat bone disease. However, thedemineralizationkineticswasslower than those of 17% EDTA.

Maleic acid is a mild organic acid used as acid conditioner in adhesive dentistry. Ballal et.al reported that the final irrigation with 7%maleic acid for 1minute was more efficient than 17% EDTA in the removal of smear layer [20].

Iodine Compounds are bactericidal, fungicidal, and virucidal. 2% iodine in 4% potassium iodide has been used in endodontic. It shows less toxicity and a decreased tendency to stain dentine. The main advantage of Iodine is that it is less irritating and toxic. However it is not the first choice as an irrigant. Despite its antimicrobial activity, iodine is a very potent allergen thereby causing a risk for allergy [21]

Curcuma longa (Turmeric): Curcumin, a member of a ginger family possesses anti-inflammatory,anti-oxidant,anti-microbial andanti-canceractivity In an in vitro study conducted by PrasannaNeelakantan, it has been shown that curcumin has significant anti-bacterial activity against E.faecalis and can be used as an alternative to sodium hypochlorite for root canal irrigation [22, 23].Thus this herb can be used especially in endodontics for root canal failure cases.

Complications during Root Canal Irrigation

Root canal irrigation is an integral part of the rootcanal treatment to ensure proper debridement and disinfection of the root canal system. The most frequently used irrigants are sodiumhypochlorite and hydrogen peroxide, or the combined use of both .Their benefits, goodtissue dissolving and disinfecting capability, have been demonstrated in several investigationsA review of these complications have been described briefly below, which necessitates the need to carry out effective techniques in order to avoid complications . However, several mishaps during root canal irrigation have been reported like damage to the

operators or patient's eye, allergic reactions etc. In the event of an accident, emergency treatment guidelines should be applied as may be relevant to each case.

Damage to Clothing

Sodium Hypochlorite, a common bleaching agent can cause a concern of damage. Accidental spillage of minute quantities can lead to rapid, irreparable bleaching [24, 25]. When using an ultrasonic device for root canal irrigation the aerosol may also cause damageto the clothing. These mishapsshould be prevented by proper shield of thepatients' clothing. When using hand irrigation, oneshouldreassure that the irrigation needle and syringe aretightly attached and will not get detached during transferor irrigation in order to prevent leakage over clothing.

Damage to the Eye

Mild burns with the alkali such as sodium hypochlorite can result in significant injury causing blurring of vision and patchy coloration of cornea [26].Irrigant in contact with patients or operators eyes can result in immediate pain, intense burning and erythema. Immediate ocular irrigation with large amounts of tap water or sterile saline should be performed by the dentist.

Damage to Oral mucosa and Skin

Skin injury with an alkaline substance requires an immediate irrigation with water as alkalis combine withproteins or fats in tissue to form soluble protein complexes or soaps which could further cause irritation to the mucosa. Accidental swallowing of irrigant by patient requires proper monitoring. It is possible that skin injury can result from secondary contamination [27, 28].

Allergic reactions

Various allergic reactions to Chlorhexidine have beendescribed. It is known to elicit allergic contact dermatitis, generally after repeated application. It can also contact urticarial,photosensitivity, fixed drug eruption and occupational asthma [29].

The allergic potential of sodium hypochlorite was first reported by Sulzberger when a 32 year old female reported a rapid onset of pain, swelling and difficulty in breathing [30]. A subsequent allergy skin scratch test performed two weeks later confirmed a positive result to sodium hypochlorite. Other symptoms include burning sensation, shortness of breath [31].

Complications Arising from the Irrigant Extrusion beyond Root Canal Apex

Chemical Burns and necrosis

When sodium hypochlorite is extruded beyond the root canal into the periradiculartissues, the effect is a chemical burn leading to localized or extensive tissue necrosis. This can further lead to tissue swelling both intra orally within the surrounding mucosa and extra orally within the skin and subcutaneous tissues. The swelling could be edematous or hemorrhagic which could later produce a sudden onset of pain, associatedbleeding, acute sinusitis, ecchymosis of the mucosa [32]. This reaction of the tissues may occur within minutes or may be delayed.

Neurological Complications

The major complications includeparathesia and anesthesia affecting the mental, inferior dental and infraorbital branches of the trigeminal nerve. Patients may take several months to regain the sensory and motor functions.

Facial nerve damage was first described by Witton et al. in 2005, where the buccal branch of the facial nerve was affected in 2 cases. Both patients exhibited a loss of the naso-labial groove and a down turning of the angle of the mouth. Both patients were reviewed and their motor function, was regained after several months [33].

Upper Airway Obstruction

Without adequate tooth isolation, sodium hypochlorite can lead to the leakage of the solution into the oral cavity and ingestion or inhalation by the patient. This could result in throat irritation and the upper airway could be compromised [34]. Ziegler presented a case of a 15-month-old girl who presented a complication of root canal irrigation with acute laryngotracheal bronchitis, stridor and profuse drooling from the mouth as a result of ingestion of a high concentration of household sodium hypochlorite.

Air Emphysema

Further accidents during endodontic therapy mayoccur when the root canal is dried with compressed air,which may be expressed through the apical constrictioninto the periapicaltissues. Studies show cases of emphysema which occurs when the root canal is dried with compressed air after injecting hydrogen peroxide into it. Symptoms and signs include a rapid swelling and erythema in the region of the treated tooth, emphysema of the face, the suborbital region, and neck. The mainsymptom is a crepitus of the swelling [35].

Flare up

An endodontic flare-up is a complication of endodontic treatment which is defined as an acute exacerbation of asymptomaticpulp, after the initiation or continuation of root canal treatment. Inadvertent extrusion of irrigants beyond the apical foramen will lead to acute reactions. Excessive pressure during irrigation will cause large amounts of irrigant to come in contact with the periapical tissues, thereby a possible etiological factor for Flare up [36].

Conclusion

Based on the various case reports and endodontic literature, special attention must be drawn to the potential risks associated with the use of root canal irrigant for root canal therapy. Thus, it is

important to carry out an effective technique in order to avoid complications. In the event of an accidental extrusion of any solution, treatment guidelines should be applied as may be relevant to each case.

Abstract

Specific location on a chromosome is referred to as loci, and the variations in the nucleotide sequence at a locus are termed alleles. When different alleles of a given gene co-exist in the human population, it is called genetic polymorphism.The genetic polymorphisms may in some situations cause a change in the protein or its expression possibly resulting in alterations in innate and adaptive immunity and may thus be deterministic in disease outcome. Genetic polymorphisms may also be protective for a disease. Cytokines, such as Interleukine-1(IL-1), Interleukine-6 (IL-6) and Tumor necrosis factor (TNF-a) plays an important role in focal immunological role in periodontitis. Thus the genetic control on cytokine function affects the appearance and severity of periodontitis. IL-1 is composed of two distinct but functionally similar molecules, IL-1a and IL-1b. Both molecules are produced by macrophages, monocytes and dendritic cells.

Key Words*: Interleukin-A(889), Interleukin-B(3954), Human DNA, Composite Genotype, Polymorphism.*

Introduction

Specific location on a chromosome is referred to as loci, and the variations in the nucleotide sequence at a locus are termed alleles. When different alleles of a given gene co-exist in the human population, it is called genetic polymorphism[1]. The genetic polymorphisms may in some situations cause a change in the protein or its expression possibly resulting in alterations in innate and adaptive immunity and may thus be deterministic in disease outcome. Genetic polymorphisms may also be protective for a disease[2]. Cytokines, such as Interleukine-1(IL-1), Interleukine-6 (IL-6) and Tumor necrosis factor (TNF-a) plays an important role in focal immunological role in periodontitis. Thus the genetic control on cytokine function affects the appearance and severity of periodontitis. IL-1 is composed of two distinct but functionally similar molecules, IL-1a and IL-1b. Both molecules are produced by macrophages, monocytes and dendritic cells.

Association of IL-A-889 and IL-B-3954 in Periodontitis

IL-1a is largely a regulator of intracellular events and a mediator of local inflammation (Dinarello 1996). IL-1 single nucleotide gene polymorphisms (SNP) such as the C/T single basepair substitution in the IL-1A promoter (889) (which is more than 99% concordant with IL-1A G4845T at exon 5) and in the IL-1B13954 locus (formerly referred as IL-1B13953) have been early related to periodontitis and triggered the subsequent publication of numerous epidemiological studies[3].

IL-1 is a powerful and potent bone resorbing cytokine, it stimulates the proliferation of precursor cells of osteoblasts. It induces bone resorption through direct action on osteoclasts and independently of prostaglandin synthesis.

IL-1 compose of 2 distinct but functionally similar molecules, IL-1a and IL-1b. both these molecules are produced by Macrophages, Monocytes and Dentritic cells. Interleukin-1 (IL-1) gene cluster polymorphisms have been associated with an increased risk of developing diseases like osteoporosis, diabetic nephropathy, autoimmune disorders, periodontal disease etc[4].

The cluster of 3 IL-1 genes – IL-1A, IL-1B and IL-1RN that code for IL-1α, IL-1β and IL-ra (receptor antagonist) have been mapped to a 415-kb region on the long arm of chromosome 2 (2q13)[5,6].

IL-1 protein level in gingival fluid is one of the strongest and most consistent predictors of periodontitis severity and progression. IL-1b is a downstream regulator of osteoclastic bone resorption and matrix metalloproteinases 8, 9 and 13, which are implicated in the tissue destruction characteristic of periodontitis[7,8].

The first study of cytokine gene polymorphism was reported by Kornman. Polymorphisms of the IL-1 gene cluster have been implicated as risk or susceptibility factors for a number of diseases including adult periodontitis. This association involves a composite genotype with at least one copy of allele 2 (the rarer allele) of the IL-1A gene at nucleotide -899 located in the promoter region and one copy of allele 2 of the IL-1B gene at nucleotide +3954 located in the 5th exon[9].

Human DNA was extracted from the cellular part of the collected blood samples by means of the QIAamp pro- cedure (QIAamp Blood Kit, Kebo Lab, Go¨teborg, Sweden) and sent to the Lab- oratory of the Division of Molecular and Genetic Medicine, University of Sheffield, UK. Genotyping was per- formed without knowledge of clinical status. Allelic frequencies of single nu- cleotide variations were tested in the gene for IL-1a [IL-1A(π4845)] and in the gene for IL-1b [IL-1B(π3954)]. The common allele was designated as ‘‘1’’ and the rarer allele was designated ‘‘2’’ for each gene variant[10,11].

Composite genotype as stated by kornman refered to the presence of specific polymorphism, allele 2 at IL-1A-889 and IL-1B-3954 loci. [9,12] The prevelance of composite genotype IL-B-3954 was significantly higher in the chronic periodontitis patients(24%) than in aggressive and other types of periodontitis which was 3.3% and 7.4% respectively. This finding was in accordance with the studies that observed increased association of IL-B-3954 in chronic periodontitis in Australian and Brazilian populations [13].

Further functional studies on these SNPs have shown interesting results such as the association of the 889T variant with a fourfold increase in IL-1a levels in the gingival crevicular fluid (GCF)[14].

The polymorphism genotype directly influence the disease pathogenesis via an effect on cytokine synthesis. Allele C of IL-B-3954 is considered to be a important risk factor in chronic periodontitis[15].

This exacerbated expression of IL-B-3954 leads to incrased level of inflammation and tissue destruction. IL-1 α is about 15-fold less potent than IL-1 β which stresses the importance of IL-1 β in pathogenesis of periodontal disease than IL-1 α [16].

The composite genotype showed no association with increased GCF volume and bleeding on probing during development of experimental gingivitis; and on the clinical and radiographic regeneration results following guided tissue regeneration (GTR) therapy[17].

Polymorphisms in the IL4 and IL4RA Genes

Interleukine-4 (IL-4) is a pleiotropic cytokine, which is produced by the T helper 2 cell subpopulation and can rescue B lymphocytes from apoptosis and enhance their survival, thus promoting B-lymphocyte mediated immunity. IL-4 also downregulates macrophage function [23]. The gene for IL4 has been located on chromosome 5q31.1.

Gene polymorphisms studied in the IL4 gene are summarized in Table 6. An IL4 -590 promoter polymorphism and a 70-bp VNTR polymorphism are the most studied polymorphisms of IL4. Case–control studies have not shown any relationship between the IL4 gene polymorphims and susceptibility to CP in several different populations. However, a haplotype of IL4 polymorphisms (carriers of R-alleles in all three SNPs studied) has been associated with CP (17.0% in cases versus 11.0% in controls; OR 1.85) [23]. No association was found for the IL4RA polymorphims in a study on Caucasians [27].

Polymorphisms in the IL6 and IL6R Genes

Multiple roles have been identified for interleukine-6 (IL-6). It is released by different cell types and its secretion levels are determined by the cell type and the nature of the stimulus [25]. The IL6 gene was demonstrated to be localized on chromosome 7p21. IL6 polymorphisms affect the serum levels of circulating interleukin-6. The -174 was found to influence IL-6 expression and production. The 174 R-allele carrier individuals have decreased plasma levels of IL-6 and present lower IL6 gene transcriptional activity when compared with N/N individuals [26].

Therefore a genetically determined low IL-6 response (the 174 R-allele carriers) may hamper individual's defense against periodontal pathogens.The carriage rates of the IL6 174 R-allele varied in Caucasian populations from 44% to 54%, in Brazilian populations from 37% to 67%, and remarkably, the 174 as well as 190 and 597 loci were nonpolymorphic in a Japanese population (Table 7). Three out of six studies in Caucasian and one out of two studies in Brazilian populations have correlated the IL6 174 G>C polymorphism with susceptibility to CP. With regard to the other IL6 gene polymorphisms, the Czech study [20], suggested that the 572 polymorphism may be a protective factor to CP. Furthermore, for the other IL6 polymorphisms only single studies have been reported.

We conclude that the IL6 174 polymorphism may be associated with CP susceptibility. However, a meta-analysis of the IL6 174 polymorphisms did not show any association for this polymorphism with CP [29].

Polymorphisms in the IL10 Gene

Interleukine-10 (IL-10) is considered an antiinflammatory cytokine, downregulating the proinflammatory immune response of the monocytes and macrophages. However, the B lymphocyte stimulatory effect may also stimulate the production of autoantibodies [23]. As a matter of fact, auto-antibodies may play a role in periodontitis [24,26]. IL-10 is produced by monocytes, macrophages, and T cells and plays a role in the regulation of proinflammatory cytokines such as IL-1 and TNF-beta.

The gene encoding for IL-10 is mapped on chromosome 1q31-q32, in a cluster with closely related interleukin genes, including IL-19, IL-20, and IL-24. Several promoter polymorphisms have been described in the IL10 gene: 1087 (1082), 819 (824), 627, 592 (597), and 590. The IL-10 1082, 819, and 592 polymorphisms show strong linkage disequilibrium and form two common haplotypes. The haplotypes may be determined on basis of the IL10 592 polymorphism [15]. The R-allele of the 592 polymorphism has been associated with decreased synthesis of IL-10 in vitro and in vivo [27,28] and may lead to altered synthesis of IL-10 in response to inflammatory stimuli [29]. IL-10 has a protective role towards periodontal tissue destruction, inhibiting both matrix metalloprteinases (MMP) and receptor activator for nuclear factor-B

(RANK) systems [19,20]. Therefore the IL10 592 R-allele carriers may be less protected against bacterial challenge.

Frequency of Composite Genotype in Different Populations

The frequency of this composite genotype has been reported to be varied in different populations. In Caucasians, a prevalence of 30-40% has been reported. In the Chinese population only 2.3% were positive for composite genotype, in the Hispanics it was 23%; in a Thai population it was 1.6%.[18] Walker et al. reported a genotype-positive prevalence of 15% in an African[19].A prevalence of 11.66% of composite genotype has been found in asian population[20].

The 42.9% occurrence of the positive composite genotype found in this study is significantly higher than the 29.1% rate found in Northern European sub- jects of unknown periodontal status or the reported 36.3% prevalence in non- smoking periodontitis patients, but comparable to the 40.6% rate in Australians of essentially European heritage[11,21].

The frequencies of IL-1A-+4845 and IL-1B-+3954were significantly greater in severe periodontitis patients. The distribution of composite genotype (allele 2 of IL-1A+4845and allele 2 of IL-1B+3954) also correlated with the severity of periodontitis. Genotype-positive subjects had a higher mean bleeding index (%) when compared to genotype-negative patients[29].

A prevalence of 11.66% of composite genotype has been found in the Maharashtrian ethnic group, correlating with the severity of periodontitis. In a study evaluating the prevalence of only IL-1B polymorphism among the South Indian subjects, a higher percentage of genotype was observed among cases, but this observation did not reach statistical significant[30].

Association of IL-1 Gene Polymorphism with Coronary Artery Disease

Coronary artery disease (CAD), resulting from atherosclerosis (AS), has become the leading cause of disability and death globally.[22] Evidence suggests that inflammation and immunity play a key role in the pathogenesis of AS and CAD [23].

Patients with pro-inflammatory IL-1(þ) genotypes were at a continuum of risk for the presence of CAD, whereas patients with IL-1(–) genotypes seemed to be insensitive to the risk for CAD.The

genes encoding the pro-inflammatory cytokines IL-1a and IL-1b are among the first to be activated in the course of an inflammatory response[24]. Plasma levels of IL-1a and IL-1b show reproducible interindividual differences and oxidation of phospolipds(OxPL) And elevated level of Lp. Vascular wall cells, such as endothelial cells and smooth muscle cells, as well as macrophages and monocytes, can produce IL-1b and IL-1Ra, and these cytokines are also present in human atherosclerotic lesions[25].

Periodontitis Susceptibility Test

Single genes may contribute to susceptibility, but since we have many interactions at the gene-gene and the gene-environmental levels, the real contribution to disease outcome might not be decisive.It detects the simultaneous presence of a specific form of two interleukin genes—allele 2 at the IL1A+4845 and IL1B+3954 loci. Patients are referred to as being “genotype-positive” if both of these alleles are present. A fundamental premise of the test is that a combination of these alleles is responsible for increased secretion of IL-β, which results in a hyperinflammatory response to a bacterial challenge, thereby predisposing a person to develop severe chronic periodontitis. It is possible to perform genetic testing for several syndromic forms of periodontitis, but there is no evidence that mutations in the genes responsible for these conditions are responsible for the more prevalent forms of non-syndromic aggressive or chronic periodontitis[26,27,28].

Abstract

This review provides an overview of digital radiography as it exists, including advanced imaging such as computed tomography (CT), cone beam-CT and micro-CT as relevant to the practice of Endodontics.New image reconstruction techniques have been introduced that provide information three-dimensionally to the clinician for routine endodontic and surgical treatment planning. In addition, carious lesions of a certain size and expansions of the maxillary sinus and proximity to the roots were observed. The 3-dimensional image analysis was interesting, but detailed observations could not be made with this technique.CT presents several advantages in comparison with other methods, but otherwise has some limitations. Scanning electron microscopy, stereomicroscopy and confocal laser microscopy can be used for superficial analysis but do not provide 3D images without the requisite of sectioning the samples. Others advantages of CT are the possibility of repeated scanning and the manipulation of image using specific software. On the other hand, a limitation of CT is the impossibility of using for in vivo studies due to the radiation level of exposure.The success of endodontic therapy is directly related to the identification of all root canals for its adequate cleaning.The analysis of internal anatomy is important for knowledge of the complexity of root canal system and planning the treatment. Instrumentation techniques and instruments are evaluated to improve the removal of contamination from root canal. Root canal filling techniques and sealers should be appropriately adapted into root canal walls and the quality of obturation is commonly studied. Microorganisms are the main cause of persistent apical periodontitis and the retreatment is indicated in some cases to decontaminate the root canal system. The aim of this work is to describe the applications of X-ray microtomography in endodontic research

Key Words: *CT scan,CBCT, Root canal treatment, Advantages in dentistry*.

Introduction

Successful management of endodontic problems is reliant on diagnostic imaging techniques to provide critical information about the teeth under investigation, and their surrounding anatomy.[1,2]Since its inception, conventional radiography has remained the mainstay of imaging in Endodontics.[3]In recent decades, however, advances in medical imaging have been applied, with varying success, to the various dental disciplines[4].Among the specific imaging techniques, which have been researched as potential diagnostic and treatment planning tools in Endodontics, are digital subtraction radiology (DSR), tuned aperture computed tomography (TACT), ultrasound (US), magnetic resonance imaging (MRI) and computed tomography (CT) [5]. These imaging techniques have been slow to gain acceptance in Endodontics, for an array of different reasons. As such, conventional radiography, despite its inherent limitations, remains the default imaging system in the field[6].However, the development of cone beam computed tomography (CT) has highlighted the inadequacies of conventional radiography when assessing the unique anatomy of the maxillofacial skeleton [7].

Conventional Computed Tomography (CT) Scan

Computed tomography (CT) of the body uses special x-ray equipment to help detect a variety of diseases and conditions[8].CT scanning is fast, painless, noninvasive and accurate. In emergency cases, it can reveal internal injuries and bleeding quickly enough to help save lives.Computed tomography, more commonly known as a CT or CAT scan, is a diagnostic medical test that, like traditional x-rays, produces multiple images or pictures of the inside of the body.The cross-sectional images generated during a CT scan can be reformatted in multiple planes, and can even generate three-dimensional images[9].These images can be viewed on a computer monitor, printed on film.CT images of internal organs, bones, soft tissue and blood vessels typically provide greater detail than traditional x-rays, particularly of soft tissues and blood vessels.

Working Mechanism of CT

X-ray slice data is generated using an X-ray source that rotates around the object; X-ray sensors are positioned on the opposite side of the circle from the X-ray source. The earliest sensors were scintillation detectors, with photomultiplier tubes excited by caesium iodide

crystals[10]. Caesium iodide was replaced by ion chambers containing high-pressure xenon gas. Initial machines would rotate the X-ray source and detectors around a stationary object. Following a complete rotation, the object would be moved along its axis, and the next rotation started(10). Newer machines permitted continuous rotation with the object to be imaged slowly and smoothly slid through the X-ray ring. These are called helical or spiral CT machines. Instead of a single row of detectors, multiple rows of detectors are used to effectively capture multiple cross-sections simultaneously. [11]

In conventional CT machines, an X-ray tube and detector are physically rotated behind a circular shroud (see the image above right). An alternative, short lived design, known as electron beam tomography (EBT), used electromagnetic deflection of an electron beam within a very large conical X-ray tube and a stationary array of detectors to achieve very high temporal resolution, for imaging of rapidly moving structures, for example the coronary arteries. Cone-beam CT functionality is also an increasingly common function found in medical fluoroscopy equipment; by rotating the fluoroscope around the patient, a geometry similar to CT can be obtained, and by treating the 2D X-ray detector.[11]

Cone Beam Computed Tomography (CBCT)

Cone beam computed tomography (CBCT) is a relatively new method to visualize an individual tooth or dentition in relation to surrounding skeletal tissues and to create three-dimensional images of the area to be examined. The use of CBCT in Endodontics is rapidly increasing worldwide.[13] Compared with traditional radiographic methods, which reproduce the three-dimensional anatomy as a two-dimensional image, CBCT is a three-dimensional imaging method that offers the possibility to view an individual tooth or teeth in any view, rather than predetermined ‘default’ views. [13]Therefore, CBCT can be a powerful tool in endodontic diagnosis, treatment planning and follow-up.Currently, CBCT is used most commonly in the assessment of bony and dental pathologic conditions, including fracture; structural maxillofacial deformity and fracture recognition; preoperative assessment of impacted teeth; and temporomandibular joint imaging; and in the analysis of available bone for implant placement. [12]In orthodontics, CBCT imaging is now being directed toward 3D cephalometry. CBCT diagnosis and 3D simulations with virtual surgery and computer-assisted design and manufacture. Image guidance is an exciting advance that will

undoubtedly have a substantial impact on dentistry.Radiation dose of CBCT is minimal when compared toconventional CT scan.

Working Mechanism of CBCT

CBCT is a recent technology. Imaging is accomplished by using a rotating gantry to which an x-ray source and detector are fixed. A divergent pyramidal-or cone-shaped source of ionizing radiation is directed through the middle of the area of interest onto an area x-ray detector on the opposite side.[14] The x-ray source and detector rotate around a rotation fulcrum fixed within the centre of the region of interest. During the rotation, multiple sequential planar projection images of the field of view (FOV) are acquired in a complete, or sometimes partial, arc. This procedure varies from a traditional medical CT, which uses a fan-shaped x-ray beam in a helical progression to acquire individual image slices of the FOV and then stacks the slices to obtain a 3D representation. [15]Each slice requires a separate scan and separate 2D reconstruction.

Advantage of Cone Beam Ct over Conventional CT

CBCT is well suited for imaging the craniofacial area. It provides clear images of highly contrasted structures and is extremely useful for evaluating bone. [16]The use of CBCT technology in clinical practice provides a number of potential advantages for maxillofacial imaging compared with conventional CT:

1. **X-Ray Beam Limitation**

Reducing the size of the irradiated area by collimation of the primary x-ray beam to the area of interest minimises the radiation dose. [16]Most Cone Beam CT units can be adjusted to scan small regions for specific diagnostic tasks. In dentistry CBCT contains short and long film,short film used for particular area which reduces the radiation dose for the patients whereas long film capable of scanning the entire craniofacial complex when necessary.

2. **Image Accuracy**

The volumetric data set comprises a 3D block of smaller cuboid structures, known as voxels, each representing a specific degree of x-ray absorption. The size of these voxels determines the resolution of the image. [17]In conventional CT, the voxels are anisotropic rectangular

cubes where the longest dimension of the voxel is the axial slice thickness and is determined by slice pitch.

3. Rapid Scan Time

Because Cone Beam CT acquires all basis images in a single rotation, scan time is rapid (10–70 seconds) and comparable with that of medical spiral CT systems. [17]Although faster scanning time usually means fewer basis images from which to reconstruct the volumetric data set, motion artifacts due to subject movement are reduced.

4. Display Modes Unique To Maxillofacial Imaging

Access and interaction with conventional CT data are not possible as workstations are required. Although such data can be converted and imported into proprietary programs for use on personal computers, this process is expensive and requires an intermediary stage that can extend the diagnostic phase. Reconstruction of CBCT data is performed natively by a personal computer.[18] Because the CBCT volumetric data set is isotropic, the entire volume can be reoriented so that the patient's anatomic features are realigned[19]. In addition, cursor-driven measurement algorithms allow the clinician to do real-time dimensional assessment.

5. Reduced Image Artifact

With manufacturers' artifact suppression algorithms and increasing number of projections, our clinical experience has shown that Cone Beam CT images can result in a low level of metal artifact, particularly in secondary reconstructions designed for viewing the teeth and jaws.

Use of CT scanin Dentistry

1.A computed tomography scan is a non-invasive medical test that uses special X-ray equipment to produce multiple images or pictures of the inside of the body and a computer to join them together in cross-sectional views of the area being studied.[20]

2.Traditional panoramic X-rays performed by dentists provide only a limited two-dimensional view. While they can show the height and contour of the jaw bone, they give no indication of the bone width and density and may distort the location of the alveolar nerve.

3.Three-dimensional dental CT imaging takes the guesswork out of implants. This quick and safe diagnostic imaging exam produces life-like spatial views of the mouth that let the

surgeon determine pre-surgically if a patient is an implant candidate[20]. With 3D imaging, a surgeon can proceed with confidence, knowing the amount of bone a patient has, the distance to the alveolar nerve and the exact angles to situate the implant. Dental CT imaging is used when patients are being fitted for implants[21].

4.The more information a surgeon has about the anatomy of the patient's mouth before a dental implant, the better the outcome. Important measurements for the surgeon to know include the width and density of the jawbone ridge in order to assess implant feasibility and the exact placement of the alveolar nerve in order to prevent painful nerve damage.

5.Dental CT imaging can also help visualize nerve location prior to wisdom tooth extraction.[22]

6. In endodontics used to detect apical periodontitis,root canal anatomy and complex morphology.

Uses of Ct in Endodontics

Assessment of Periapical Periodontitis

Apical periodontitis (AP) is the principal disease associated with infection of the root canal system. Currently, the accepted reference standard for the radiological detection of AP is periapicalradiography[23] .However, in the early stages of AP, periapical bone destruction may be minimal or be masked by adjacent anatomy, such that its presence is not manifested on conventional radiographs. Periapical radiographs identified the presence of periapical lesions in 3% of the roots whilst CBCT could demonstrate the presence of AP in 14% of the paired roots. The current evidence suggests that CBCT does have a higher sensitivity compared with periapical radiography for the detection of periapical lesions. The specificity of both types of imaging systems is similar;CBCT should not be used for routine assessment of periapical disease prior to Endodontic treatment. However, it may be indicated to aid the diagnosis of (non)odontogenic pain when clinical examination and conventional radiographic assessment is not clear;CBCT should not be used for the routine assessment of the outcome of root canal treatment[24].

Assessment of Root Canal Anatomy

Investigated to compare charged-couple device and photostimulable phosphor plate digital radiography systems with CBCT to detect the number of root canals in 72 extracted mandibular incisors, first premolars and maxillary first molar teeth. They found that with

digital radiographs, regardless of the system used, Endodontists despite taking parallax radiographs failed to identify at least one root canal in 40% of teeth when compared with CBCT[25].assessed the prevalence of disto-lingual roots in mandibular first molar teeth assessed with conventional radiographs and CBCT; they found that the prevalence of disto-lingual canals was 21% and 33%, respectively, with radiographs and CBCT respectively. Cone beam computed tomography is a useful addition to the endodontists armamentarium for identifying root canals however, it should only be reserved for cases where root canal anatomy cannot be fully appreciated with existing aids, such as parallax radiographs and the dental operating microscope[25].

Pre Surgical Assessment

In addition to revealing radiographic signs of periapicalpathosis and root canal anatomy, CBCT scans accurately determine the relationship of adjacent anatomical structures to teeth with endodontic problems[26]. This clinically relevant information may be useful for treatment planning and the subsequent management of the tooth in question. Cone beam computed tomography should only be considered when existing radiographic techniques do not yield adequate diagnostic information, such as the proximity of the root apices (and associated periapicalpathosis) to neighbouring anatomical structures (e.g. the maxillary sinus and inferior dental canal)[27].

Applications of Dental Trauma Assessment

Radiographic assessment is essential for establishing a differential diagnosis of my traumatic dental injuries.Intra-oral views can help to identify the location, type and severity of the traumatic dental injuries[28] .In addition, periapical radiographs can help to assess: stage of root development in young permanent teeth, periapicalpathosis and the correlation of displaced primary teeth with developing successors and proximity of pulp tissue with tooth fractures[28].

Diagnosis and Management of Root Resorption

Due to its often quiescent onset, varying clinical presentation and potential to affect any part of the root’s external surface or canal wall, the detection of root resorption is often challenging. The definitive diagnosis of root resorption is ultimately dependent on the

radiographic demonstration of the disease process, which in turn is limited by the diagnostic potential of the imaging device used to determine its presence[29].

Advantages of CT

1.There are several advantages that CT has over traditional 2D medical radiography. First, CT completely eliminates the superimposition of images of structures outside the area of interest. Second, because of the inherent high-contrast resolution of CT, differences between tissues that differ in physical density by less than 1% can be distinguished[30].

2.Finally, data from a single CT imaging procedure consisting of either multiple contiguous or one helical scan can be viewed as images in the axial, coronal, or sagittal planes, depending on the diagnostic task. This is referred to asmultiplanar reformatted imagin[30].CT is used in medicine as a diagnostic tool and as a guide for interventional procedures.

3.Sometimes contrast materials such as intravenous iodinated contrast are used. This is useful to highlight structures such as blood vessels that otherwise would be difficult to delineate from their surroundings. Using contrast material can also help to obtain functional information about tissues[31].

4.The software necessary for CT data reconstruction can be run on personal computers, potentiating its use as a chairside diagnostic and treatment planning tool. In addition, multiple slices can be scrolled through in real time producing dynamic images. Cursor driven measurements allow dimensional assessments to be made, again in real-time.

5. In addition, basic image manipulations are possible[32].Window levels can be adjusted, specific areas can be magnified and annotations can be added[32].Surface rendering software is also available.

6.The scan times achievable with CT are short and comparable with panoramic radiography. This is beneficial in that the likelihood of patient movement during the scan is less. In addition, the CT hardware is much large and more expensive than CBCT machines. Therefore, CT is well suited to use in dental practice[33].

Limitations of CT

1. Computed tomography imaging is sometimes affected by radiographic artifacts related to the X-ray beam.

2. When the CT X-ray beam encounters an object of very high density, such as enamel or metallic restorations, lower energy photons in the beam are absorbed by the structure, in preference to higher energy photons.

3. The result is that the mean energy of the X-ray beam increases[34].This is called 'beam hardening' and the phenomenon produces two types of artifact: distortion of metallic structures, called 'cupping artifact', and the appearance of streaks and dark bands between two dense structures.

4. These artifacts can reduce the diagnostic yield of the images.Furthermore, patient movement during the scan can adversely affect the sharpness of the final image[34].

Technical Consideration

CT radiation dose and digital image quality:

The effective dose of CT scans is higher than periapical and panoramic radiography. The effective dose varies between scanners[34]. It is also dependent on the region of the jaw being scanned, exposure settings of the CT scanner, the size of the field of view (FOV), exposure time (s), tube current (mA) and the energy/potential (kV)[28]. An image always contains a degree of ‘noise’, that is, false grey scale level of a single pixel, which may influence thequality of the image generate [35].Too low mA causes noise in the image, conversely a higher mA decreases the amount of noise; however this comes at an increased radiation dose to the patient. Endodontic CT imaging should offer not only 3D assessment of the region of interest, but also generate the images with an adequate spatial resolution to allow detailed assessment of the tooth and the surrounding alveolar anatomy[36].CT systems have significantly lower spatial resolution than intra-oral radiographs[29].

Dose Reduction and Optimisation

To ensure patient safety, personnel who use a CT scanner must have appropriate training and knowledge of patient radiation doses related to the specific CT scanner they are using. For endodontic purposes, the FOV should be limited to the region of interest, that is, the FOV should encompass the tooth (or teeth) under investigation and its surrounding structures. This is an effective way to reduce the patient dose[37].The tube current (mA) selected should be as low as possible, so that the image produced is of sufficient diagnostic yield even though there may be a degree of noise[38].The effective dose is also dependent on the region of the oral cavity being scanned[39].

Conclusion

The decision to expose a patient to a CT investigation must be carried out on a case-by-case selection. The potential benefits of the CT scan should outweigh the potential risks. Radiology is constantly evolving[40].clinicians must regularly update their core knowledge in CT. Postgraduate endodontic programmes should incorporate the use of CT into their curriculum to ensure graduates are competent[41].The impact of CT on decision-making in endodontic treatment planning requires further investigation[42].

Abstract

A review to identify the current status and the usage of Cone BeamComputed Tomography(CBCT) imagining in orthodontics.Cone beam computed tomography (CBCT) has been a vital tool for imaging diagnostic tool in orthodontics. The utilisation of CBCT for diagnosis and treatment planning has been facilitated by the relative advantages of three-dimensional (3D) over two-dimensional radiography.The current diagnostic and treatment planning indications for CBCT include TMJ morphology and pathology contributing to malocclusion, impacted teeth, cleft lip and palate and skeletal discrepancies requiring surgical intervention,Other situations such as rootresorption, supernumerary teeth, temporomandibular joint (TMJ) pathology, asymmetries.The purpose of this review is to highlight the clinical use of CBCT in orthodontics.Although the history and clinical examination are of prime importance, the use and evolution of three-dimensional (3D) CBCT for imaging is more accurate for diagnosis and treatment planning.

Key Words: *Cone beam computed tomography, Malocclusion, Orthodontic treatment, TMJ, Cleft lip and Cleft palate.*

Introduction

Comprehensive visualisation and records of the craniofacial complex have always beenimportant goals in orthodontic imaging. These tasks have routinely been performed by means of plaster models, photographs and radiographs. Current imaging techniques in the dental office are essentially two-dimensional (2D) representations of three- dimensional (3D) objects. These 2D projections, suffer from several limitations like magnification, distortion, superimposition and misrepresentation of structures[1]. However, cone-beam computed tomography(CBCT) has gained considerable acclaim worldwide in recent years as a viable 3D imaging modality.

CBCT in dentistry is high resolution, low distortion, digital imaging of the hard tissues of the head. Instead of pixels, the resolution is measured in voxels and often is sharper than a conventional CT. Cone-beam refers to the cone shape of the X-ray beam, unlike conventionalCT, which uses a fan-shaped beam to create multiple thin slices[2]. CBCT produces panorex and cephalometric projections, which become 3D when the data is reformatted in a volume. With CBCT technology all possible radiographs can be taken in under 1 minute. The orthodontist now has the diagnostic quality of periapical, panoramic, cephalograms, occlusal radiographs, and TMJ series at their disposal, along with views that cannot be produced by regular radiographic machines like axial views, and separate cephalograms for the right and left sides.

Malocclusion is a three-dimensional problem resulting from vertical, transverse and anterior-posterior discrepancies in the teeth, maxilla or mandible. It comes as little surprise that orthodontists immediately welcomed the 3-D rendering capacity of cone beam computed tomography (CBCT) as a means to optimise diagnosis and treatment planning of malocclusion[3]. CBCT imaging provides accurate measurements, improves localisation of impacted teeth, provides visualisation of airway abnormalities, it identifies and quantifies asymmetry, it can be used to assess periodontal structures, to identify endodontic problems, to plan placement sites for temporary skeletal anchorage devices, and to view condylar positions and temporomandibular joint (TMJ) bony structures of orthodontic diagnosis[4].This review will cover CBCT use in orthodontics.

Three-dimensional CBCT based hard and soft tissue simulations, photographic integrations and superimpositions have ushered in a new era of dynamic CBCT imaging. Future developments in this field offer promises of even greater benefits in orthodontic diagnosis and treatment. The long awaited incorporation of the 3D to our radiographic records is soon becoming a reality. CBCT is the future of orthodontics and the applications in orthodontics seem almost limitless.

Types of Computed Tomography

Computed tomography can be divided into 2 categories based on acquisition x-ray beam geometry; namely: fan beam and cone beam.

In fan-beam scanners, an x-ray source and solid-state detector are mounted on a rotating gantry. Data are acquired using a narrow fan-shaped x-ray beam transmitted through the patient. The patient is imaged slice-by-slice, usually in the axial plane, and interpretation of the images is achieved by stacking the slices to obtain multiple 2D representations. The linear array of detector elements used in conventional helical fan-beam CT scanners is actually a multi-detector array[5]. This configuration allows multi-detector CT (MDCT) scanners to acquire up to 64 slices simultaneously, considerably reducing the scanning time compared with single-slice systems and allowing generation of 3D images at substantially lower doses of radiation than single detector fan-beam CT arrays[1].

CBCT Working Principle

A CBCT scan with a single revolution of the radiation source is sufficient to scan the entire maxillofacial region. CBCT technology is based on the use of a cone-shaped X-ray beam that is directed through the patient and the remnant beam is captured on a flat two-dimensional (2D) detector[6]. The X-ray source and detector are able to revolve about a patient's head, and a sequence of two-dimensional (2D) images is generated. These 2D images are then converted into a 3D image using computer software. The rapid movement of the X-ray tube and digital detector through 180°, or more frequently through 360°, produces essentially instantaneous and precise 2D and 3D radiographic images of an anatomical structure[7].

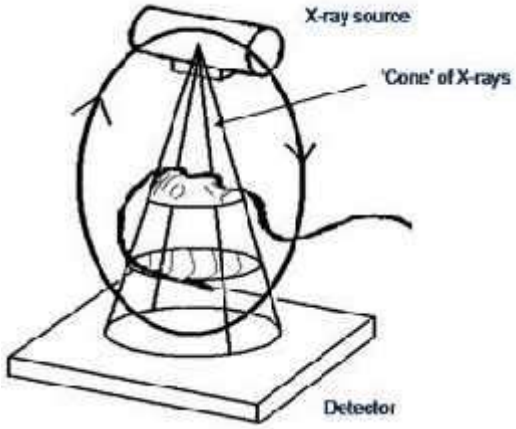

Figure 1: Working principle of CBCT

CBCT Orthodontic Application

Since the introduction of CBCT in the late 1990s, it has become well established as an effective radiographic tool for oral and maxillofacial diagnosis. CBCT is being utilised for many of the same applications CT has been used for in the past. However, with its improved characteristics, such as lower radiation and improved accessibility and affordability, it is being employed to a much greater degree in orthodontic diagnosis and treatment planning. The applications of CBCT in orthodontics include assessment of palatal bone thickness,skeletal growth pattern, severity of tooth impaction, and upper airway evaluation for possible obstructions[8]. CBCT is helpful in treatment planning of orthodontic cases which need buccal tooth movement and arch expansion.In general, orthodontics has relied on 2D X-rays to assess 3D structures. However, CBCT provides a 3D visualisation of the craniofacial skeleton, and this has applications in various orthodontic situations.

Table 1: CBCT in Diagnosis

Diagnosis	Assessment of skeletal structures and dental structures
	Skeletal jaw relation

	Symmetry/asymmetry
	3D evaluation of impacted tooth position and anatomy
	Growth assessment
	Pharyngeal airway analysis
	Assessment of TMJ complex in three dimension
	Cleft palate assessment

Treatment planning	Orthognathic surgery treatment planning in true 1:1 imaging
	Planning for placement of temporary anchorage devices (TADs)
	Accurate estimation to space requirement for unerupted/impacted teeth
	Used in association with CAD/CAM techno logy for construction of custom appliances.

Radiation Dose Considerations

The decision for any radiographic imaging procedure should be performed following the as-low-as-reasonably-achievable (ALARA) principle[9]. CBCT can be justified only if the anticipated information does have the potential to change a patient's treatment modalities or

outcome. Radiation risk has most often been estimated by calculating the effective dose of a CBCT scan and comparing this value to the following: 1) measurements obtained from comparable imaging modalities, 2) background equivalent radiation time or 3) radiation detriment. Often, the base unit of these comparisons (typical panoramic dose, background radiation, weighted probabilities of fatal and nonfatal cancers) is variable and not absolute [10]. This implies that depending on the panoramic image dose used for the comparison, the risk of CBCT may be reported either conservatively or liberally compared with the risk of panoramic radiography. Because CBCT exposes patients to ionising radiation that may pose elevated risks to some high-risk patients (pregnant or younger patients), elaborate explanations and disclosure to patients about radiation exposure risks, benefits, and imaging modality alternatives are crucial and should be documented in the patient records[11].

Application in Orthodontic Diagnosis

Impacted Teeth Evaluation

CBCT is commonly used to assess an impacted tooth and its position.Research has shown that enhanced precision in the localisation of canine teeth and improved estimations of the space conditions in the arch can be obtained with CBCT, and this can greatly affect diagnosis and treatment planning to facilitate a more clinically-orientated approach [12]. Small volume CBCT is also justified as a supplement to routine panoramic X-rays in the following cases: when canine inclination in the panoramic X-ray exceeds 30°, when root resorption of adjacent teeth is suspected, and/or when the canine apex is not clearly discernible in the panoramic X-ray, implying dilaceration of the canine root[13]. When comparing conventional radiography and CBCT, found that CBCT provides more information regarding the location of pathology, the presence of root resorption, and treatment planning. However, the benefits of CBCT imaging must be weighed against the radiation risk to paediatric patients and the complexity of the pathology involved.Ectopic cuspids are a relatively common occurrence the orthodontist must address. The ectopic or impacted incidences of maxillary cuspids is only second to that of the third molar; and has been reported by various authors in ranges that fall between 0.92% and 3%[7,8]. Impactions are twice as common in females as in males.Maxillary impactions are most often located palatally (85%) and of the patients with maxillary impactions, approximately 8% are bilateral[14]. The prevalence of mandibular impactions (0.35%) is much lower than that of maxillary impactions.Surgical

removal of impacted teeth demands precise knowledge of the tooth location in the jaw and its relation to other teeth and surrounding anatomical structures[15].

Bone Quality and Quantity Assessments

With the widespread use of temporary anchorage devices (TADs), the determination of bone volume, bone quality, and the location of adjacent structures have become important in providing orthodontic treatment. It has been shown that a location 4 mm palatal to the incisive foramen provides excellent bone volume for palatal bone screws[16]. A technique using high-resolution CBCT scans and rapid prototyping to fabricate surgical guides has also been described for placing TADs on the buccal aspect of the jaws.

Tooth-Bone Relationships

For orthodontic treatment purposes, the boundary conditions may be defined as the amount (depth and height) and morphology of the alveolar bone relative to tooth root dimensions, angulation, and spatial position[17]. The complex anatomical boundary conditions may limit or dictate the planned or potential tooth movement as well as the final desired spatial position and angulation of the tooth. Patients with alveolar bone phenotypes that clinically appear too narrow to accommodate significant labiolingual or buccolingual displacements or angulations of teeth, patients with compromised periodontium or gingival anatomy or both, and patients in whom the movement of the tooth or teeth may entail translocation past another tooth or obstruction may benefit from CBCT scans for assessing tooth-bone relationships [10,11].

Orthodontic Implant Placement

The knowledge of the root positioning can greatly enhance the opportunity for proper placement and success of orthodontic implants. CBCT images allow more accurate and dependable views of the inter-radicular relationships than panoramic radiographs. CBCT data can be used to construct placement guides foe positioning mini-implants between the roots of adjacent teeth in anatomically difficult sites[18]. The volume and quality of the bone in the proposed placement sites can be evaluated before insertion of the mini-implants.

Orthognathic Surgery

Several applications of CBCT in orthognathic surgery treatment simulation, guidance and outcome assessment have been developed. CBCT 3D surface reconstructions of the jawbones are used for preoperative surgical planning and simulation in patients with traumas and skeletal malformations. Coupled with dedicated software tools, simulations of virtual repositioning of the jaws, osteotomies, distraction osteogenesis and other interventions can now be successfully implemented[19].

Root Morphology and Resorption

Root length, root form and root resorption have traditionally been assessed via periapical radiographs. CBCT imaging becomes a preferred method for diagnosis by orthodontists because of its three dimensional rendering capability. Root position and morphology are critical issues for an orthodontist as it may affect the final occlusion[20]. Root anatomy, such as short or dilacerated, is a determinant factor for the amount and direction of a tooth movement. Furthermore, because of the concerns about external root resorption, orthodontistsneed to get precise measurement of root angulation and length before treatment. Using CBCTimages also provide detailed information about dysmorphic roots. Root positioning and morphology might be indicators of a disease[21]. Of course, all root anomalies are not identical, but when supported with genetic testing, CBCT imaging will be helpful in interpreting anomalous root morphology in syndromic cases.

CBCT could provide enhanced visualisation of roots, making it a valuable tool for assessing pre-orthodontic or post orthodontic root resorption. The mean difference between direct and radiographic CBCT measurements of root length has been shown to be 0.05 mm(SD ¡e. 0.75)[22]. Although these differences were statistically significant for some teeth, the statistical analysis appears not to have corrected for multiple comparisons performed in the study that would have diminished the number of significant differences found. Also determination of measurement error of in vivo root lengths showed an error of approximately 0.2 mm in the pre-and post-treatment measurements[23]. Although these finding some value in the use of CBCTin determining root resorption and morphology, additional studies assessing the efficacy and sensitivity of CBCT in detecting root resorption and evaluating root morphology are recommended.

Supernumerary Teeth

A supernumerary tooth may closely resemble the teeth of the group to which it belongs. In supernumerary cases, radiographic examination aims to determine the localisation and the morphology of the supernumerary teeth. As it is critical to decide which teeth to be extracted and which teeth to be retained, CBCT helps to precisely evaluate the position and morphology of these teeth. It is also possible to detect any contact between the supernumerary teeth and adjacent teeth and to evaluate their relation with other anatomical structures[24]. The information obtained from CBCT images also facilitates the determinationof the optimal surgical access to these teeth in order to minimize harm to adjacent teeth and to surrounding tissue.

Location of Anatomical Structures

Anatomic structures, such as the mental foramen, inferior alveolar nerve, maxillary sinus, and adjacent roots are easily visible using CBCT. CBCT images also allow precise measurement of distance, area and volume which helps the clinicians in treatment planning for sinus lifts, ridge augmentations, extractions and implant placements[25].

Fractured Root

To view root fractures radiographically, it may be difficult if the fracture is in an oblique direction. With CBCT, the tooth of interest can be viewed in all the three planes of space making it easier to determine the site of root fracture and degree of displacement.

TMJ Assessment

The temporomandibular joint (TMJ) is a complex entity with hard and soft tissue components. TMJ disorders (TMDs) are common but widely variable. MRI has sustained its position as the gold standard imaging modality for diagnosing TMDs since it provides excellent visibility of the disk and the associated joint muscles[26]. CBCT para-sagittal and coronal slices show clear images of the condylar head and the glenoid fossa.Additionally, provides images from different orientations and different reconstruction views thus providing axial, coronal and para-sagittal imaging of the condylar head. CBCT is more accurate than panoramic radiography and conventional tomography for detecting TMDs. CBCT exam was also recommended before image-guided puncture operation of the superior compartment of the joint space[18].

Asymmetry Evaluation

Three-dimensional visualisation of the patient allows for a more accurate evaluation of both dental and skeletal asymmetries. Presence of truly unilateral crossbite vs one subsequent to a shift of the mandible into centric occlusion can be determined more easily by viewing and measuring the maxillary and mandibular bones in three dimensions.

Cleft Lip and Cleft Palate

CBCT for patients with cleft lip and palate is useful for both preoperative and therapeutic evaluations.In cleft lip and palate patients, information regarding the number and orientation of teeth, dental and skeletal age, the amount and quality of available bone and bone graft in the cleft region are considered vital for the clinical management.CBCT imaging of the TMJ complex with panoramic radiography and linear tomographic views, and found that the CBCT images were more accurate and showed superior reliability in diagnosing condylar morphology disturbances and erosion[12]. For a complete bilateral TMJ exam, an average of four tomographic cuts in both the lateral and frontal planes are needed for each TMJ. In addition, scout images preceding the actual tomography are needed. In comparison, a CBCT examination requires less time, it includes image data for both the right and left TMJs from a single 360° rotation scan around the patient's head, and it simplifies patient positioning.

Additional advantages include a potentially lower radiation dose and the possibility of views and image manipulation in the form of rotated views. Medical CT is typically used to quantify the amount of bone present. Yet, the young age of cleft patients makes the routine use of medical CT problematic due to the relatively high radiation dose involved[14]. CBCT is rapidly replacing medical CT for this task since it provides excellent 3D visualisation of the palate at the pre-maxilla region at a lower patient dose. CBCT is used to determine dental age and when a large scan field of view FoV selection is available, 3D reconstructions of the cervical vertebra can be made and employed to determine skeletal age. Additionally, CBCT has been used to show any deformities in the piriform margin in the nasal platform and the antero- posterior depression of the nasal alar base.Three-dimensional CBCT reconstructions of the skin surface of the face and nose for cleft lip assessment are also possible[16,17].

Pathologies of Jaw

Presence of radiopaque lesions near the apexes of teeth, such as exostosis, condensing osteitis, dense bone island and focal apical osteoporosis are not readily visualised on

panoramic radiographs. They appear to have no causative factors but can prevent tooth movement. Such lesions can be viewed easily using CBCT images.

Airway Analysis

The CBCT technology provides a major improvement in the airway analysis, allowing for its three- dimensional and volumetric analysis. Airway analysis has conventionally been carried out by using lateral cephalograms[27]. Three-dimensional airway analysis will be useful in understanding the reasons why clinical conditions like sleep apnoea and enlarged adenoids affect the way clinicians manage these complex conditions and alveolar height, especially when multiple units are proposed. This has improved the clinical success of these prostheses, and led to more accurate and aesthetic outcomes in oral rehabilitation.

The introduction of CBCT technology means that both the cost and effective radiation dose can be reduced, suggesting that its frequency of use may increase. The CBCT has already been in use in implant therapy and may be exploited in orthodontics for the clinical assessment of bone graft quality following alveolar surgery in patients with cleft lip and palate[27]. The images produced resulted in greater precision in the evaluation of bone sites and, therefore, gave the clinician a better chance of restoring the site with implants and also influenced the decision-making process of whether to move teeth orthodontically into the repaired alveolus.

Dentofacial Deformities and Craniofacial Anomalies

Evaluation of changes in the craniofacial region during growth and with treatment using lateral cephalograms makes a great contribution to the science of orthodontics. However, in recent years, researches discussed the validity of evaluating a 3D craniofacial structure in a 2D plan. CBCT imaging can provide valuable information about dentofacial deformities and craniofacial anomalies, like facial asymmetry which affects three dimensions of the face, and it can be used to simulate virtual treatment plans for orthopaedic corrections, orthognathic surgeries and distraction osteogenesis[28]. By capturing images and analysing the craniofacial hard and soft tissues and by generating virtual patient models, CBCT imaging permits the clinicians to reposition and reconstruct craniofacial structures.

Application in Orthodontic Treatment Planning

Many of the applications of CBCT in conventional orthodontics also apply in combined orthosurgery treatments. In fact, 3D CT has already been applied to a much greater extent in maxillofacial surgery than in orthodontics[29]. Several applications of CBCT in orthognathic surgery treatment simulation, guidance and outcome assessment have been developed. CBCT3D surface reconstructions of the jawbones are used for preoperative surgical planning and simulation in patients with traumas and skeletal malformations. Coupled with dedicated software tools, simulations of virtual re-positioning of the jaws, osteotomies, distraction osteogenesis and other interventions can now be successfully implemented. Pre and post-operative 3D CBCT skull models can also be registered (i.e. superimposed on each other) to assess the amount and position of alterations in the mandibular rami and condylar head following orthognathic surgery of the maxilla and the mandible 3D reconstructions of the jawbones from CBCT are of sufficient quality for clinical work[27,28].In addition, databases may be interfaced with the anatomical models to provide characteristics of the displayed tissues to reproduce tissue reactions to development, treatment, and function.

Estimation of Space Requirement of Unerupted or Impacted Teeth

CBCT scans enable the accurate localisation of impacted and/or transposed teeth, and this helps determine the best method for surgical access and bond placement. It also helps delineate the ideal and most efficient path for extrusion into the oral cavity to circumvent or decrease collateral damage [18]. Furthermore, CBCT scans provide the orthodontist with valuable information regarding the teeth neighbouring the impacted teeth in terms of root proximity. This information can then be used to place adjacent teeth and their roots away from the traction path of the impacted tooth so as to avoid untoward changes in these teeth[30]. Another advantage of CBCT over conventional radiographs is its capacity to obtain precise dimensions of an impacted tooth, which aids in estimating and creating the necessary space to accommodate the tooth within the arch.

Superimposition

The introduction of CBCT allows clinicians to perform superimpositions in three-dimensions and has eliminated some of the errors that occur with traditional lateral cephalometric superimposition. These 3D superimpositions help in better assessment of treatment outcomes.

Conclusion

CBCT is a valuable tool, and it is particularly important in cases where conventional radiography cannot provide adequate diagnostic information. The use of CBCT imaging is justified when it benefits to the diagnosis and/or treatment plan outweigh the potential risks of exposure to radiation in the presence of individual anamnesis, clinical inspection, and available radiographs. The decision for any radiographic imaging procedure should be performed following the ALARA principle. CBCT can be justified only if the anticipated information has the potential to change a patient's treatment modalities or outcome. CBCT can be used when there is a controversy between the adequacy of conventional radiographs and 3D imaging. These cases include cleft palate patients, assessment of unerupted tooth position, and identification of root resorption caused by unerupted teeth, and planning orthognathic surgery. The later includes cases of cleft palate, craniofacial syndromes, supernumerary teeth, assessment of multiple impacted teeth, and identification of root resorption caused by impacted teeth, and planning for orthognathic surgery. CBCT imaging may also be applied to other types of cases in which it is likely to provide valuable diagnostic information following verification of a positive benefit.

Abstract

It is well established that smoking contributes to the development of lung disease and cardiovascular disease, and there is evidence that it has a considerable influence on oral health. Smoking has many negative effects on the mouth, including staining of teeth and dental restorations, reduction of the ability to smell and taste, and the development of oral diseases such as smoker's palate, smoker's melanosis, oral candidiasis and dental caries, periodontal disease, implant failure, oral pre cancer and cancer, in which the latter is obviously the most serious tobacco-related effect in the mouth. However, importance has been attached to periodontitis, which affects a large proportion of the population, and during recent years more attention has been given to implant survival rates. As tobacco accounts for such a high proportion of these diseases, comprehensive tobacco control policies are required to make progress in reducing the burden of tobacco-related oral diseases. Effective treatments to prevent tobacco use and increase cessation are available and need greater implementation. Dental practices must provide a uniquely effective setting for tobacco prevention and cessation.

Key Words: *Smoking, Tobacco, Pre-Cancerous Lesions, Periodontitis, Dental Caries*

Introduction

Tobacco is one of the major toxic agents in our civilization. Tobacco comes from a plant that is native to America, around Peru and Ecuador(1). Tobacco was introduced to Europe from America in the fifteenth century, first being used in medicinal purposes. Later, it came to be burnt in pipes for pleasure on a large scale for nearly 100 years in Europe as well as the rest of the world. Pipe smoking gave way to the use of tobacco as snuff and in time to cigars and cigarettes varying from country to country, until cigarette smoking became the dominant form in most of the developed countries between the two world wars(2).Cigarette smoke is highly dynamic and has a complex matrix consisting of a gas phase and a particulate phase with more than 3800 compounds. Among these compounds,60 of them are well-established carcinogens in animals and 15 of them are carcinogens in humans. Some of the carcinogens found in cigarette smoke include polycyclic aromatic hydrocarbons, aldehydes, arsenic, nickel and cadmium(3). Smoking not only harms smokers but also harms the people around them.

Forms of Tobacco and its Pattern of Use

Tobacco is used in both smoke and smokeless forms. Smoking forms are more common in western countries compared to the Middle East and eastern countries. Smoking form includes the use of beedis and cigarattes predominantly with various aids like hooka, hookli, chutta, dhumthi, chillum. However the higher pricing of these products compared to other forms makes this more common amongst the middle and upper socioeconomic classes of population. Beedi is a smoking stick made by rolling a dried piece of rectangular temburni leaf (Diospyrosmelanaxylon) with sun-dried, flaked tobacco arranged in a conical shape. The roll is then secured with the thread. Chutta is a kind of reverse smoking wherein the burnt end is kept inside the mouth. It is made up of coarsely prepared roll of tobacco and prevalent in South-eastern parts of India. Dhumthi is another type of smoking forms made by rolling the tobacco leaves inside the leaf of the jackfruit tree. Hooka is made using metallic or wooden pipes and used for smoking tobacco. This device consists of a spherical receptacle containing water with aromatic substances. The tobacco products pass through the water into the smoking pipe. Hookli is another form of smoking tobacco device which employs a short clay pipe like device. Chillum is a conical clay pipe used to smoke tobacco and tobacco with ganja in northern parts of India. The narrow end of this device is put inside the mouth and wrapped in a wet cloth to act as a filter(4). The smokeless

forms of tobacco includes betel quid, khaini, mawa, snuff, gutka and pan masala. Betel quid consists of areca nut, slaked lime, tobacco mixed and folded in a betel leaf and placed either in the buccal or labial vestibule. Khaini is prepared by mixing roasted tobacco flakes and slaked lime and the mixture is placed in the lower buccal or labial sulcus. Mawa is a mixture of areca nut, tobacco and slaked lime. Snuff is a blackish brown powder obtained from tobacco through roasting and pulverisation. It is generally used through nasal insufflations or applied on the gums using a finger. Gutka is a mixture of areca nut, tobacco and few other condiments and marketed in different flavors n colorful pouches. Pan masala may or may not contain tobacco, with areca nut and few other condiments(5).

This article further gives a short review about the effects and oral conditions associated with smoking and tobacco intervention in dental practice.

Oral Conditions Associated With Smoking

Oral PrecancerousLesion

Leukoplakia

Smokeless palate and smoker’s melanosis

Oral candidiasis and hairy tongue

Oral Cancers

Squamous cell carcinomas of the

• Tongue

• Floor of the mouth

• Lip

Verrucous carcinomas of the

• Buccal mucosa

• Gingiva

• Alveolar ridge

Periodontal Diseases

• Increased plaque and calculus depositions

• Ischaemia

- Gingival inflammation
- Periodontal pockets
- Gingival recession
- Alveolar bone loss

Dental Caries and Saliva

Peri-Implantitis

Aesthetics, Halitosis and Taste Derangement

Leukoplakia

Leukoplakia is believed to be a premalignant lesion associated with development of oral cancer (6). Tobacco smoking is the most important known etiological factor in development of oral leukoplakia. Cross-sectional studies show a higher prevalence rate of leukoplakia among smokers, with a dose-response relationship between tobacco use and oral leukoplakia, and intervention studies show a regression of the lesion after the cessation of smoking(7). Leukoplakia of the floor of mouth appeared to be significantly more often present in smokers than in non-smokers(8). Smokers have a six-fold increase in the risk of developing leukoplakia of the oral mucosa regard to non-smokers.

Smoker's Palate and Smoker's Melanosis

Palatal leukokeratosis**(**smoker's palate**)** is an asymptomatic lesion associated with heavy pipe and cigar smoking usually appearing as white changes in hard palate, often combined with multiple red dots located centrally in small elevated nodule. It may disappear after smoking cessation(9),(10). It does reveal premalignant potential. Melanin pigmentation of the oral mucosa is normally seen in coloured races. Among Caucasian heavy smokers, 30% prevalence in pigmentation is seen, mostly on the attached gingiva(10). A recent study in the Indian population showed that smokers were more likely to develop smoker's melanosis compared to other lesions(11)

OralCandidiasisandHairyTongue

Cigarette smoking is associated with a variety of changes in the oral cavity and it has an effect on oral commensal bacteria and fungi, mainly Candida species, which causes oral candidiasis. How cigarette smoke affects oral Candida is still controversial(12). Further studies and research need to find the exact etiology of smoking and oral candidiasis. It has been seen in the clinical experience that some Candida infections disappear following smoking cessation alone. Another oral lesion, “hairy tongue” or “black hairy tongue” is a benign condition characterized by hypertrophy of the filiform papillae that give the dorsum of the tongue a furry appearance associated sometimes with heavy smoking (13), but its etiology remains unclear.

OralCancer

Cigarette smoking and use of other types of tobacco products cause oral cancer (14). Oral cancer affects mostly middle aged or elderly people and is more common in men than in women. It constitutes 2-3 % of all cancers worldwide. Cigarette smokers have two to five times higher risk of oral cancer than that of non-smoker, the risk increasing with the number of cigarettes and years smoked. Tobacco-specific N-nitrosamines, aromatic amines, and polycyclic aromatic hydrocarbons presented in mainstream tobacco smoke are considered the major carcinogens contributing to the risk of oral cancer from smoked tobacco products (15). Although the underlying mechanisms are not known in detail, it is said that smoking could lead to cancer because carcinogens in tobacco smoke can induce changes in DNA. In recent years much attention has been given to smoking related mutations in a tumor suppressor gene coding for p53 protein. This protein is important in regulating cell proliferation and has a role in the repair of DNA damage (16). Smoking-related mutations in the gene may lead to an accumulation of DNA damage in the cells, which may play an important role in the development of cancer. It has been estimated that between 75 % and 90 % of all cases of oral cancer can be explained by the combined effect of smoking and alcohol use. This could be because alcohol dissolves certain carcinogenic compounds in tobacco smoke and also alcohol increases the permeability of the oral epithelium. Smoking and excessive alcohol intake increases the risk of the development of oral cancer.

Periodontitis

Periodontal diseases, including gingivitis and periodontitis, are common human bacterial infections that affect the gingiva, periodontal tissues and bone supporting the teeth. Gingivitis is a form of inflammation limited to the marginal gingival tissues, and is usually caused by the accumulation of plaque due to inadequate oral hygiene. Periodontitis refers to the destructive inflammation that results in irreversible loss of periodontal attachment and tooth-supporting alveolar bone(17). Gingival recession may result from periodontal destruction and exposure of part of the root surfaces of teeth to the oral environment. The exposed root surfaces are at risk of developing root surface caries. Acute necrotizing gingivitis is also strongly correlated with tobacco use(18). Although the precise cause of this disease remains unknown, it tends to occur most frequently in teenagers and young adults. Tobacco smoking may exert a masking effect on gingival symptoms of inflammation, which might give the smoker a false sense of assurance of gingival health(19). Smoking upregulates the expression of pro-inflammatory cytokines, such asinterleukin-1, which contributes to increased tissue damage and alveolar bone resorption(20). Interleukin-1 genotype positive smokers are more susceptible to severe adult periodontitis(21).

DentalCariesandSaliva

Few studies have shown a relationship between smoking and a higher incidence of dental caries (22),(23). There is no evidence of any direct etiological relationship, but the findings of higher counts of lactobacillus and, although various results are reported, presence of Streptococcus mutans in smokers (24)may explain this relationship.

Tobacco usage stimulates salivary flow, but there isno long term effect on saliva flow rates. Over longer time periods smokers may have slightly reduced pH and buffering power compared to nonsmokers. A recent study showed that smoking is associated with lower salivary cystatin activity and output of cystatin C during gingival inflammation (25).

Peri-Implantitis

Peri-Implantitis is the formation of deep mucosal pockets around dental implants, inflammation of the peri-implant tissues, and increased resorption of implant surrounding bone. Chronic peri-implantitis may lead to implant failure,if left untreated(26). Tobacco use may directly compromise the osseointegration of root-form dental implants(27). The combination of smoking and inflammationinduced by local deposits like plaque and calculus significantly promotes bone loss around the implants(28), whereas occlusal loading has only a minor role.

Aesthetics, HalitosisandTasteDegeneration

Discoloration of teeth, dental restorations and dentures are very frequent among smokers and is more severe than that caused by tea and coffee consumption. Smoking is found to be associated with halitosis(29). It has been seen that smoking influences the decreased function of smell and it is also associated with worsening of taste perception(30).

TobaccoInterventioninDentalPractices

The primary goal is to ensure that every patient who uses tobacco is identified and offered at least a brief intervention at each clinical visit. Tobacco intervention can be either by behavioral or pharmacological management.

BehavioralManagement

Following is the summary of the suggested guidelines(31)

Ask

Askpatients about smoking. A system should be implemented that ensures that every patient at every visit is asked about tobacco use, and the answer documented in the patient’s record.

Advise

Adviseall smokers to stop the habit. The health care professional or the dentist should provide the patients with information and advice, reinforcing the patient's own motivation when possible and emphasizing the benefits of stopping. Dentists should demonstrate the oral effects of tobacco

if present, or inform patients about the increased risk of poor response or healing after dental procedures relevant to the patient (31).

Assess

Assessthe patient's willingness to stop. If the patient is willing to make an attempt to quit, dentists should assist the patient. Dentists should ensure that the patient is aware of the staff's willingness to help, for instance by providing the patient with written information or/and asking the patient in a subsequent visit to reconsider his or her decision (31).

Assist

Assist the patient in stopping the habit. If a patient has a desire to stop, the dentist should help the patient set a realistic quitting date which should be soon but not immediately, so that the patient has time to prepare. If consultation time is limited, self-help materials that provide the patient with necessary information about smoking cessation can be provided. Nicotine replacement therapy (nicotine gum, inhaler, nasal spray, or skin patch) can be very helpful(32). Whatever the approach, the dentist should see to it that the patient leaves the office with a concrete plan for stopping and information about how to prepare for the quitting date and how to successfully stop, keeping in mind that most smokers relapse three to five times before succeeding in stopping.

Arrange

Arrange follow-up contact. Follow-up contacts are very important as the chances of a successful outcome are improved when patients know their progress will be reviewed. The dentist should confirm the quitting date, show continuing support, and follow through if the patient was successful or encourage another try if unsuccessful. If possible the dentist should arrange to see the patients within one or two weeks after the quitting date and consider a second follow-up one or two months later (32).

It is important that the entire dental team is aware of the relationship between smoking and oral conditions associated with smoking. The clinical staff should be familiar with current facts and encouraged to actively participate in tobacco intervention routines.

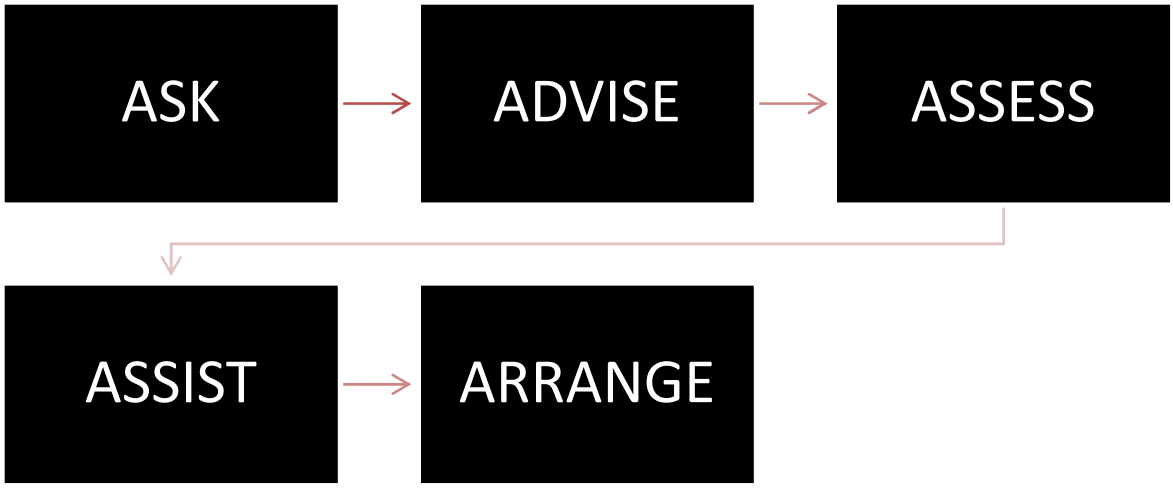

Figure1: The five A's in behavioral tobacco interception

PharmacologicalManagement

The Food and Drug Administration (FDA) has approved five nicotine replacement therapy products for smoking-cessation: Sustained-release bupropion and four nicotine-replacement products such as a gum, a transdermal patch, a nasal spray and a vapor inhaler.

Nicotine ReplacementTherapy

Nicotine replacement therapy provides an alternative form of nicotine to relieve symptoms of withdrawal in a tobacco smoker who is abstaining from tobacco usage. The patch provides a stable, fixed dose of nicotine over a period of 16 to 24 hours. The other nicotine replacement products have a more rapid onset and a shorter duration of action, allowing the user to adjust the dose of nicotine. Blood nicotine levels peak 5-10 minutes after the administration of nicotine nasal spray, 20 minutes after chewing nicotine gum or using a vapor inhaler and 2 to 4 hours after applying a transdermal nicotine patch. The nicotine gum and the inhaler have similar pharmacokinetic properties since, both are absorbed through the oral mucosa. For heavy smokers, the nicotine gum containing 4 mg of nicotine per piece is more effective than that

containing 2 mg per piece (33). The use of all nicotine-replacement products increases the long-term rates of smoking-cessation and relieves cravings for nicotine and symptoms of nicotine withdrawal.

Non NicotineTherapy

Bupropion, an antidepressant with dopaminergic and noradrenergic activity, was efficacious for smoking-cessation when combined with counseling. Other medications like nortryptyline, Selective Serotonin Reuptake Inhibitors like fluoxetine, paroxetine, sertraline, citalopram and Monoamine oxidase inhibitors like moclobemide, selegiline, lazabemide and also antidepressants like tryptophan, imipramine, doxepin, venlafaxine are also used in tobacco cessation (34).

Conclusion

Periodontal diseases, oral cancers, and precancerous development are linked closely with the tobacco usage. Advising patients to quit tobacco use is a dental professional responsibility, and the dental professionals must take an active role in nicotine replacement counseling. Smoking cessation should be incorporated as an integral teaching component of the undergraduate dental curriculum, particularly with respect to the prevention and diagnosis of tobacco-induced oral lesions and complications. Close collaboration of both dentists and physicians with smoking cessation programs must be advocated in the treatment of tobacco-smoking patients.

Dental Anomalies in Pre-Term Children: A Review

Ruksana Sheik[1], Gifrina Jayaraj [2],Jayanth Kumar V[3]

Graduate Student[1], Senior Lecturer[2], Department of Oral Pathology, Reader[3], Department of Oral Medicine and Radiology,

Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstract

Preterm and low birth weight children comprise approximately 6% of live births. Apart from medical problems they also have dental anomalies. Studies have shown a high prevalence of generalized enamel hypoplasia in the primary dentition of around 40-70 per cent in preterm children which is likely to be associated with low bone mineral stores. Other dental defects observed in preterm children are localized enamel hypoplasia, crown dilacerations, and palatal distortions which are usually associated with traumatic laryngoscopy. The current review would analyse the dental anomalies in preterm children so as to be aware of the possible anomalies they might develop the children can also be monitored and treatment intervention can be done at an early stage.

Key Words:*dental defects, low birth weight, preterm, tooth anomalies, tooth eruption*

Introduction

Prematurity

Preterm births which occur prior to 37 weeks gestation comprise approximately 6 per cent of all live births in developed Western nations. The birth weight of preterm children is often well below that of the average birth weight of 3.3 kg, with the lowest birth weights being experienced by those with the shortest gestational ages. The survival rates of preterm children range from >95 per cent for those with birth weights 2000-2500 g to around 50 per cent for those with birth

weights of 700-800 g. With increasing sophistication of neonatal care in recent years, the survival rates of the most preterm children have improved dramatically, even neonates with birth weights of around 500 g having a 10 per cent chance of survival. [1,2] A number of etiological factors for premature birth exist, many of which are associated with maternal and fetal diseases, but often the cause remains obscure (Yu, 1989), and inborn factors of the child may be of importance. The immaturity of many organs makes a prematurely born infant more prone to neonatal complications and systemic derangements, and there is also interference with the developing teeth, especially those that are at a critical stage at the time of the insult.[3] Many studies about the growth and development of preterm infants with low birth weight indicate that, although some complications may be present on the physical growth some time after birth, they are usually corrected by catch up growth (the growth that occurs at a higher rate than estimated for the age and gender of the child in response to nutritional rehabilitation).[4,5]

Complications of Prematurity

Premature infants are poorly prepared for extrauterine life. Especially, very early and early preterm infants require many weeks of intensive neonatal care. Many serious complications may occur in nearly all the major organ systems. The brain, the lungs, and the eyes are the most susceptible organs. Furthermore, the infants are at increased risk of infections either at or shortly after birth or at a later age. (6,7) Because premature infants often have respiratory distress syndrome resulting from immature lung tissues and a deficiency of surfactant (the mixture of lipoproteins excreted by the alveolar epithelium that lowers surface tension), they have to be treated with oxygen ventilation through an oro-oronasotracheal tube in combination with surfactant administration. Oxygen can also be supplemented with continuous positive airway pressure. (7) Infants aged 35–36 gestational weeks are mature enough to suck and swallow milk. Less mature infants will need to be fed with breast milk supplemented with proteins, calories, and minerals through an oro-or nasogastric tube. (7)

The early and long-term effects of birth prematurity on the physical and psychological growth and development of the child are subjects of considerable current interest. Most studies have indicated that in early childhood preterm children show significant delay in many areas of

physical and psychological growth and development. Although ‘catch-up’ growth has been reported in later childhood, some studies have indicated that long-term delays into adolescence may occur. [3]

Pre term children, especially early preterm children, were shorter, had lower weight, and had a smaller head circumference than full-term controls. (8)Also, less muscle mass has been reported among pre term children. (9)Behavioral symptoms observed in pre term children included increased rate of hyperactivity, difficulties in concentration, and below-grade-level performance at school. (8,10)

In a study conducted by Benjamin et al, 100 (5.55%) pregnancies resulted in Low birth weight neonates out of total 1800 pregnancies. Out of 100 low birth weight infants, 93 survived beyond four weeks of life. (11)

Oral Defects

Like other tissues and organs of the body, the facial bones and dentition can be affected by premature birth. Most studies on oral defects have shown that premature birth can cause enamel defects, classified as quantitative loss of enamel (hypoplasia), qualitative change in the translucence (opacity) of the enamel, or a combination of both. These effects are usually located on the primary teeth, which are undergoing mineralization around the time of the premature birth, although even permanent teeth can be affected.(12)
The pathogenesis is considered multifactorial, the most important factor being calcium disturbances in the neonatal period. However, contributing causes of the enamel defects include local trauma from laryngoscopic and endotracheal intubation, which abuts against the maxillary anterior alveolar ridge.(13)

Other defects, such as notching of the alveolar ridge, palatal grooving, high arched palate, dental crossbite, and palatal asymmetry, have also been reported with higher frequencies when compared with full-term controls. Moreover, delayed eruption and developmental defects of both the primary and permanent dentitions have also been noted.(12)

Many of the studies considering altered morphology have also highlighted that pressure from the oro-or nasotracheal tube or direct trauma from the laryngoscope when the tube is placed might account for the defects.(14)
Thus, the presence of the tube on the palate can conceivably inhibit a normal growth process, and it has also been discussed whether altered morphology of the alveolar ridge and palate can be eliminated by compensating remodeling and growth.(13)
Conceivably, the altered palatal morphology can lead to an increase in malocclusions such as crossbite, resulting in an increasing need for orthodontic treatment. Moreover, changes in the path of eruption of teeth, which can influence the occlusion and tooth spacing, can also contribute to an increasing need for orthodontic treatment.

Oral Complications

Studies suggest that birth is the stimulus for tooth eruption and the eruption time is the same in preterm infants as for full-term infants. (15)
Delayed dental eruption and dental caries are more significant in preterm children as compared to the full term infants. This increased risk is due to local trauma and systematic factors including neonatal asphyxia, respiratory distress syndrome, hyperbilirubinemia and neonatal infection. Premature loss of teeth and malformation of the oral cavity can lead to speech and appearance problems.(16) The prevalence of dental defects is significantly higher in prematurely born children than in their full term counterparts, including enamel hypoplasia, which are reported to exist in both the primary and permanent dentitionand are thought to be associated with a number of systemic derangements typical of pre-term birth, notably hypocalcaemia, metabolic and nutritional disorders, neonatal infections and respiratory distress syndrome.(3)
Prematurely born children show an increased prevalence of developmental defects in enamel in the primary dentition The incidence can be as high as 96%. It has been shown that children born preterm also have an increased frequency of enamel defects in the permanent dentition. However, few studies have been made concerning enamel defects in the permanent dentition of children born preterm and none has prospectively studied both primary and permanent dentitions in the same children.(3)

Primary Dentition

In a study conducted, the mean mesiodistal dimensions of the teeth appeared to be directly related to birthweight, with the very low birthweight groups showing the smallest dimensions and the normal birthweight groups showed the largest dimensions. The low birthweight groups showed measurements in between those of the very low birthweight and normal birthweight groups.(17)

In case of maxillary central incisors, in the very low birthweight group, the mean mesiodistal dimension was 9% less as compared to the normal birthweight group children. In case of maxillary lateral incisors, In the very low birthweight group, the mean mesiodistal dimension was 11% less as compared to the normal birthweight group. (18)

The mandibular central and lateral incisors of the very low lowbirthweight children has the smallest dimensions as compared to the normal birthweight children. (18)

In another study conducted, all 15 children showed dental defects of the primary dentition. Three children (20%) had only dental opacities. In 7 other children, the opacities and hypoplasia were present in different teeth. These opacities, which consisted of white or yellow brownpatches, were located mainly on the buccal and occlusal surfaces. 12 children (80%) showed hypoplasia of at least one tooth. The teeth most commonly showing hypoplasia were the maxillary primary central and lateral incisors followed by the maxillary and mandibular canines. On the other hand, the mandibular first primary molar and canine were the teeth most commonly showing opacities followed by the mandibular second primary molar. (19)

In a study comparing three birthweight groups including a control group of normal birth weight (NBW) children, Seow and co-workers reported a direct relationship of birthweight and gestational age with the prevalence of enamel defects, that is, the VLBW group showed a very high prevalence of enamel defects of over 70 per cent, compared with 50 and 20 per cent in the LBW andNBW gr o u p s respectively. (18) .This high prevalence of enamel defects in the primary dentition of the VLBW group had been confirmed in two more recent studies. (20,21)

Permanent Dentition

In another study conducted 13 (33%) VLBW children showed enamel opacity of at least one permanent tooth, and another four (10%) had enamel hypoplasia of at least one permanent tooth,

giving a total prevalence of 17 (43%) children affected with enamel defects. In contrast, only six (15%) of the NBW children had enamel opacity, and another four (10%) had enamel hypoplasia of at least one permanent tooth,giving a total prevalence of 10 (25%) children with enamel defects. Overall, the prevalence of enamel defects in the VLBW group was significantly higher than the NBW group. (22)

In the VLBW group, four (3%) of the 141 permanent first molars examined showed enamel hypoplasia, and 24 (17%) showed enamel opacity, yielding a total of 30 (20%) teeth affected with enamel defects. Of the NBW children, identical numbers of first permanent molars with enamel hypoplasia compared to the VLBW group were found. Only 10 (8%) teeth were affected with enamel opacity, giving a totalof 14 (11%) teeth affected with enamel defects. The difference in total prevalence of enamel defects in the permanent first molars between the two groups was statistically significant. In contrast, in the case of the permanent central incisors, although the VLBW group showed a slightly higher percentage of enamel defects (5%) than the NBW group (2%), the difference was not significant. However, in the case of the permanent lateral incisors,there was a prevalence of enamel defects of 12% in the VLBW compared with 0% in the NBW group. (22)

One other report,which included a group of 38 premature children with at least one maxillary incisor, gave a prevalence of enamel hypoplasia in the permanent central incisors of 58%, but other permanent teeth were not examined. (23)

Conclusion

Preterm children have a higher prevalence of enamel defects than normal birth weight children. They also have a higher prevalence to enamel hypoplasia. Also the tooth eruption and development is significantly delayed in preterm infants as compared to normal birth weight children. Further research has to be done to get a better insight about pre term children and the dental anomalies associated with them.

Abstract

Dental diseases are the most prevalent chronic diseases worldwide, and a costly burden to health care services.The treatment of dental diseases is expensive, accounting for between 5% and 10% of total health care expenditures in industrialized countries. In most developing low-income countries, the prevalence rate of dental caries is high and more than 90% of caries is untreated. An estimated 5 billion people worldwide suffer from dental caries (tooth decay).Dental diseases include dental caries, developmental defects of enamel, dental erosion and periodontal disease. In low-income countries, the cost of restorative treatment of dental disease is disproportionately expensive. In order to overcome this, many researches have been conducted to study the uses of plant extracts for treating dental diseases. Grape seed extract(GSE) known as Vitisvinifera.L.These natural extracts are observed to possess various therapeutic uses.This is attributed to the presence of proanthocyanins. Grapes are consumed all over the world and their seeds are rich in phenolic compounds, with an ability to damage microbial cells by exerting an influence on the selective permeability of the plasma membrane, which results in the leakage of vital intercellular substances. GSE has exhibited promise as a source for the manufacture of new generations of antibacterial agents for dental uses without exerting an influence on the biological equilibrium in the oral cavity. Various researches have been conducted to assess their medicinal uses across various fields of Health sciences.This review focuses on the healing and therapeutic uses of GSE in dental treatments.

Key Words:GSE,dental,antibacterial,biofilm.

Introduction

Oral diseases and conditions, including dental caries, periodontal disease, orofacial disorders, and tooth loss, affect more persons than any other disease [1].Oral diseases and/or disorders can affect a person's overall health[2]. Dental caries is a multi-factorial infectious disease that depends on diet and nutrition, microbial infection, and host response. Although the introduction of fluoride has resulted in the reduction of dental caries, the latter is still the most common infectious disease in humans and is especially prevalent in children and people with xerostomia (dry mouth) [3]. In adults, the incidence of root caries was found to increase dramatically with age. Thus, control of caries is of major importance in dentistry and will continue to be for the foreseeable future. Besides dental caries, gingivitis and periodontal disease affect most of the adult population, with the prevalence of severe disease increasing with age [4]. Recent research has shown that oral bacteria may contribute to increased risk of heart attacks, strokes, and lung disease and may be associated with premature childbirth in some women [5,6].Root caries is especially prevalent among the elderly population due to gingival recession and the exposure of susceptible root surface[7].Proanthocyanidin (PA) is a naturally occurring plant metabolite widely available in fruits, vegetables, nuts, seeds, flowers, and bark[8].Commonly used as natural antioxidants and free-radical scavengers, PA has been proven to be safe in various clinical applications and as dietary supplements [9,10]. Grape seed extract (GSE) is a rich source of PA, which has been reported to strengthen collagen-based tissues by increasing collagen cross-links [11]. PA from cranberries inhibited the surface-adsorbed glucosyltransferases and acid production by *S. mutans* [12]. Studies have also shown that PA increased collagen synthesis and accelerated the conversion of soluble collagen to insoluble collagen during development [13,14]. PA-treated collagen matrices were demonstrated to be nontoxic and resisted enzyme digestion in vitro and in vivo [15]. Xie et al. [16] performed a study to examine the effect of GSE on the remineralization and demineralization of the collagen-rich root tissue of human teeth.The following summarizes some of the studies related to grape seed extract and their potential oral health benefits.

Grape Seed Extract and Dental Uses

Addition of Grape seed extract renders phosphoric acid a collagen-stabilizing etchant.

Studies found that grape seed extract (GSE), which is rich in proanthocyanidins, could protect demineralized dentin collagen from collagenolyticactivities following clinically

relevant treatment. Because of proanthocyanidin's adverse interference to resin polymerization, it was believed that GSE should be applied and then rinsed off in a separate step, which in effect increases the complexity of the bonding procedure. The present study aimed to investigate the feasibility of combining GSE treatment with phosphoric acid etching to address the issue. It is also the first attempt to formulate collagen-cross-linking dental etchants. Based on Fourier-transformed infrared spectroscopy and digestion assay, it was established that in the presence of 20% to 5% phosphoric acid, 30 sec of GSE treatment rendered demineralized dentin collagen inert to bacterial collagenase digestion. Based on this positive result, the simultaneous dentin etching and collagen protecting of GSE-containing phosphoric acid was evaluated on the premise of a 30-second etch- ing time. According to micro-Raman spectroscopy, the formulation containing 20% phosphoric acid was found to lead to overetching. Based on scanning and transmission electronic microscopy, this same formulation exhibited unsynchronized phosphoric acid and GSE penetration. Therefore, addition of GSE did render phosphoric acid a collagen-stabilizing etchant, but the preferable phosphoric acid concentration should be <20% [17].

Anti-Arthritic Activity of Grape Seed Ethanolic Extract.

Inflammation is a complex biological process and is an initial response to tissue injury.it is mediated by the release of autacoids and usually precedes the development of the immune response. Rheumatoid arthritis is an auto immune disorder which affects the adult population worldwide. Grape seed extract commonly known as vitisvinifera. It contains proanthocyanidins, a polymer of Catechin molecule. It has antioxidant and free radical scavenging, Anti microbial, Anti diabetic, Immuno modulatory, Anti cariogenic, Hepato protective activity. Grape seed extract exhibits significant anti arthritic activity. The ethanolic seed of Grape extract shows an inhibitory activity at 200-1000mg/ml by inhibiting denaturion of protein and its effect was compared with standard drug diclofenac sodium. Auto antigen production in rheumatoid arthritis is due to denaturation of protein. From the results of the present study it can be stated that ethanolic extract of Grape seed is capable of managing the production of auto antigen and inhibiting the protein denaturation in rheumatoid arthritis [18].

Caries

Dental caries is an infectious microbiological disease of the teeth that results in localized dissolution and destruction of the calcified tissues. It is the second most common cause of

tooth loss and is found universally, irrespective of age, sex, caste, creed or geographic location. It is considered to be a disease of civilized society, related to lifestyle factors, but heredity also plays a role. In the late stages, it causes severe pain, is expensive to treat and leads to loss of precious man-hours. However, it is preventable to a certain extent. The prevalence of dental caries in India is 50%–60%.Dental caries is especially prevalent among the elderly population due to gingival recession and the exposure of susceptible root surface [5].Proanthocyanidin (PA) is a naturally occurring plant metabolite widely available in fruits, vegetables, nuts, seeds, flowers, and bark [7].PA has been proven to be safe in various clinical applications and as dietary supplements [8,9]. Grape seed extract (GSE) is a rich source of PA, which has been reported to strengthen collagen-based tissues by increasing collagen cross-links [19].

Remineralisation

The high consumption of energy drinks can lead to tooth erosion [20].Malinauskas et al. showed that energy drink consumption levels were high in university students, 51% of them routinely drinking energy drinks to improve their ability to exercise and function in daily life [21].Rabobank's research in 2011 indicated that energy drink sales growth will increase by 15%in the next 5 years in Indonesia, confirming a high level of energy drink consumption. This consumption was influenced by a city lifestyle and daily business [22]. Energy drinks have a low pH, which can cause tooth erosion. However, the acidity level alone is not sufficient to predict the erosive potential of energy drinks. The erosive potential is further influenced by the low degree of hydroxyapatite and fluorapatite saturation and the presence of cirate, a substance that can eliminate calcium from saliva and teeth [23].

Demineralization can be prevented by restoring tooth mineral components through the process known as remineralization. Common remineralization agents include fluoride, casein-phosphopeptide– amorphous calcium phosphate (CPP-ACP), and beta-tricalcium phosphate (β-TCP) proven to prevent caries [24,25,26]. Remineralization can also be achieved with natural ingredients that have been used for a long time as medications. One example is grapeseed extract, a supplement that is often used as an antioxidant and is known to contain proanthocyanidin (PA); this extract is an effective remineralization agent [27]. In 2008, Qian Xie et al. showed that application of a 6.5% grapeseed extract could contribute in remineralization of dentin in permanent tooth roots [28]. Research concuted by Mahkameh et

al. In 2013 also showed that a 12.5% grapeseed extract had a positive effect on the remineralization process of primary tooth enamel surfaces [29].Grapeseed extract applied to the enamel surface acted as a remineralization agent by depositing minerals onto lesion surfaces by forming an insoluable complex when mixed with phosphate buffer [27].

Biofilm Inhibition

The inhibitory effects of GSE on biofilm formation are dose dependent. Higher concentrations in the extracts led to a fall of its effectiveness, principally caused by its poor dissolution in water.But it is also observed that these inhibitory effects are less effective than those of chlorhexidine. Thus their clinical efficiency has been evaluated to further improvise their actions that can exceed artificial equivalents [28,29].

Uses of Grape Seed Extract in Inflammatory Diseases.

Periodontal diseases (gingivitis and periodontitis) are chronic inflammatory diseases, which are generally caused by gram-negative bacteria, and feature gingival inflammation. Lipopolysaccharide is a cell wall component of gram-negative bacteria, which inhabit in almost all the subgingival tissues, and acts as pathogenic and exacerbating factors for periodontal diseases through inflammatory response [30,31,32]. One of the main targets of LPS is human gingival fibroblasts (hGFs) that play a pivotal role in inducing periodontal tissues injury through cytokine production such as IL-6 and IL-8 [33,34,35].

Thepretreatment of human gingival fibroblasts (hGFs) with grape seed extract (GSE) containing proanthocyanidin for 1 min elicited cytoprotective effects upon hGFs exposed to harsh environmental conditions; short-term exposure of hGFs in the mitotic phase to pure water or physiologic saline resulted in the low recovery of viable cells [36]. GSE pretreatment improved the recovery of cells exposed to pure water or physiologic saline. In addition, hGFs exposed to GSE for 1 min were proliferous, even after culture in a serum-free medium. In that study, it was also shown that intracellular formation of reactive oxygen species (ROS) induced by culture in serum-free medium was inhibited in cells pretreated with GSE for 1 min. Those results suggested that, because of its cytoprotective effects, GSE could be a novel prophylactic and/or therapeutic agent for oral injury. Several studies have shown that polyphenols (including proanthocyanidin) can protect cells. For instance, the reduced cell viability and oxidative stress in HepG2 cells induced by tert-butyl hydroperoxide can be

mitigated by treatment with proanthocyanidin for 6 h [37].Also, ellagic acid has been shown to ameliorate the cytotoxic effect of paraquat (1,1′-dimethyl-4,4′-bipyridinium dichloride) on human alveolar A549 cells *via*its antioxidant action [38].In addition, epigallocatechin-3-gallate shows a cytoprotective effect on mycotoxin-induced cytotoxicity in the human colon adenocarcinoma cell line HT29 through anti-oxidative and anti-inflammatory mechanisms [39]. Also, lemon grass (*Cymbopogoncitratus*Stapf) polyphenols can protect human umbilical vein endothelial cells from oxidative damage induced by high glucose, hydrogen peroxide (H_2O_2), and oxidized low-density lipoprotein [40]. Such studies suggest that cytoprotective effects are exerted *via* the antioxidant action of those polyphenols.

Grape Seed Extract and Oral Squamous Cell Carcinoma.

Oral squamous cell carcinoma (OSCC) poses an important health concern all over the world. Standard treatment plan for oral squamous cell carcinoma depends on the stage of the disease. Early-stage tumors are treated primarily by surgery or radiotherapy, with both modalities resulting in similar local control and survival rates. More advanced carcinomas often require multi-modality therapy with surgery, radiation and chemotherapy, which can result in very high morbidity [41]. Treatment modalities of oral SCC have numerous side effects. Radical surgery can result in disfigurement and functional impairment. Common side effects of radiotherapy include mucositis, oral candidiasis, loss of taste and xerostomia, which may be permanent due to the detrimental effect of radiation on salivary glands [42]. Osteoradionecrosis of bones within the radiation field (most commonly the mandible) may occur as a result of damage to the bone vasculature and osteocytes and is one of the most seriouscomplications of radiotherapy [43]. Current chemotherapeutic drugs exert many cytotoxic effects on normal cells, resulting in adverse systemic and cytotoxic effects and development of resistance to therapy in OSCC patients. Despite continuing research and advances in treatment, the clinical outcomes for HNSCC have not improved significantly over the last several decades, with the overall 5-year survival rate as low as 50% [44,45,46];therefore, development of new treatment modalities is crucial for prevention and to reduce mortality. Herbal medicines (plant-derived compounds), in combination with routinely implemented treatment modalities, such as radiotherapy and surgery, can reduce morbidity and mortality in OSCC patients. Recent studies focus on herbal medicines as potent anti-cancer drug candidates. Previous studies have revealed the anticancer activities of herbal extracts against oral squamous cell carcinoma cell lines. These include Tamoxifen in

combination with Cisplatin, 5-Fluorouracil, Cordycepin, Scutellariabaicalensis, Quercetin and Artemisinin. In a study by Ghashmet et al, time-and dose-dependent inhibitory effect of anti-proliferative activity of local honey (Tualang) on OSCC and HOS cell lines was investigated by MTT assay, light and fluorescent microscope, and Annexin V-FITC Apoptosis Detection Kit [47].In a study by Hseu et al, ethanol (70%) extracts of *Alpiniapricei* rhizome could induce G2/M phase of the cell cycle arrest and apoptosis in KB cells [48].Grapes (*Vitisvinifera*) are rich in flavonoids, polyphenols, anthocyanin, proanthocyanidins, trans- resveratrol, and procyanidins. Recent studies have revealed that GSE has antioxidant and free radical scavenging activities, and anti-diabetic, cardioprotective, hepatoprotective, anti-carcinogenic, antimicrobial, and anti-viral effects. Dinicola et al showed that GSE has anti-proliferative and apoptotic effects on CaCO2 and HCT-8 colon cancer cell lines [49] Sun et al [50] indicated that GSEs have the ability to inhibit HNSCC cell invasion by targeting the expression of EGFR and activation of NF-κ B as well as inhibiting the epithelial-to-mesenchymal transition In the present study, for the first time the cytotoxic effects of the grape seed extract was investigated and their possible effects on cell death properties in KB cell line were determined. Furthermore, the probable side effects of the grape seed extract on HUVEC were evaluated. The results showed that grape seed extract inhibited the growth of oral squamous cell carcinoma through the induction of apoptosis. The IC50 values strongly indicated that the GSE had a potent cytotoxic effect on KB cells. The crucial results of our study addressed to selectivity of GSE effects on KB vs. HUVEC cells (effect was observed on KB, but HUVEC cells) indicate possibility for its promising use for its promising use for the treatment oral squamous cell carcinoma. The different sensitivities of human oral squamous cell carcinoma and normal cells to GSE suggested that used GSE may be used as a natural chemotherapeutic drug. Many chemotherapeutic agents can trigger the apoptosis of cancer cells. Morphological changes in apoptosis are chromatin condensation and nuclear fragmentation. Apoptotic DNA fragmentation is a key feature of apoptosis, characterized by the activation of endogenous endonucleases with subsequent cleavage of chromatin DNA into internucleosomal fragments of approximately 180-200 base pairs (bp) [51,52]. The results of our study showed induction of apoptosis in the cancer cells as a result of treatment with the GSE. Cell death assay, TUNEL and DNA fragmentation analyses were used to reveal if induction of apoptosis was achieved by GSE. It was shown that DNA fragmentation happened in the late stage of apoptosis. *In vitro* study have shown an anticancer potential of the GSE and selectivity to

inhibit growth and induce apoptosis in KB, unlike HUVEC cells. However, additional experiments should be done to test grape seed extracts effect on other cancer cell lines *in vitro* and *in vivo* (animal studies) conditions to establish their therapeutic ability as well as its adverse effects.The results show that polyphenol-containing extracts inhibited S. mutans. Both red and green grape extracts had higher activity than the other fruits tested, and extracts of grape seed were more active than those from grape skins. The highest activity was P70 extract from red grape seeds. The flavan-3-ol and procyanidin oligomer content of grapes can vary with the variety, degree of maturity and part of the fruit studied. It is known that the degree of con- densation of polyphenols differs in different parts of ber- ries. The skins of red and white grapes contain higher con- centrations of catechin and epicatechin whilst grape seeds contain higher concentrations of oligomericprocyanidins [53]. This is consistent with the results obtained here.

GSE against S.mutans.

Organisms present in biofilms such as dental plaque are also more resistant to antimicrobial agents [54].However, the extracts also inhibited adhesion of S. mutans, suggesting that they inhibited glucosyltransferaseactivity and inhibit glycan formation as has been shown for specific polyphenols from oolong tea [55]. The double action of inhibiting growth and adhesion may help in preventing plaque formation and inhibition of acid production may reduce damage to teeth by pre-formed plaque. The extracts of plants containing high levels of polyphenols inhibited growth of S. mutans and other bacteria. Inhibition of S. mutans occurred in the presence of both sucrose and glucose, two of the main sugar com- ponents used in confectionery and food products and acid production was inhibited. Adhesion of S. mutans was also inhibited, suggesting that glycan synthesis was also inhibited. The extracts may have a role in caries prevention.

GSE and Bleaching

In this study, the grape seed extract (proanthocyanidin) group demonstrated the highest bond strength which makes it a viable alternative to sodium ascorbate. Proanthocyanidins are high molecular weight polymers that comprise the monomeric flavan-3-ol catechin and epicatechin. They are found in natural sources such as grape seed extract, pine bark extract, cranberries, lemon tree bark and hazel nut tree leaves in high concentrations. It has been proven to be safe for use in dietary supplements since it is a naturally occurring plant

metabolite. The reversal in reduction of bond strength by proanthocyanidins has been attributed to their specificity for hydroxyl free radicals, the presence of multiple donor sites that trap superoxide radicals and esterification of epicatechin by gallic acid which enhances the free radical scavenging ability [56,57].ARI scores indicated that the most common site of bond failure was at the bracket/adhesive interface or within the 9 adhesive in all the groups except the immediate bonding group, which showed bond failure closer to the enamel/ adhesive interface and the difference was statistically significant. This was consistent with the lower bond strength values found in this group. The bond failure at the bracket/adhesive interface and within the adhesive seen in the ceramic brackets was similar to that found by Oztas et al. [58] and indicated that risk of enamel damage was reduced. Bleaching with 35% hydrogen peroxide immediately before bonding reduces the bond strength of ceramic brackets. A delay in the bonding procedure by one week reverses the reduction in bond strength. Treating the bleached enamel surface with 10% sodium ascorbate solution or grape seed extract (5% proanthocyanidin solution) also reverses the reduction in bond strength and can be used as an alternative to delayed bonding.

Reactive Active Species Inhibition

Periodontitis is initiated by the sub-gingival biofilm but it's progression is attributed to the presence of reactive oxygen species[59]. Excess of reactive oxygen species release is implicated in the inflammatory process[60]. Thus the antioxidant activity of GSE inhibits ROS which ultimately leads to inhibition of periodontitis[61].

Antibacterial Effect of GSE

GSE used in this work showed antibacterial activity against Campylobacter spp., being the MIC lower than 20 mg/l and the MBC 60 mg/l. Phenolic acids and catechins, were the main responsible of the growth inhibitory effect of GSE. As MIC and MBC values of the GSE are in the range between 10 and 100 mg/l, this extract could be considered as a promising antibacterial agent (62), potentially useful for the control of Campylobacter in foods. Identification and quantification of the individual phenolic compounds of GSE could be useful to standardize the production process to obtain an enriched extract to inhibit Campylobacter growth. The fact that grape seed is sold commercially as dietary supplement and also has Generally Recognized as Safe (GRAS) status approved by Food and Drug Administration

(FDA), could facilitate its potential use in different points of the food chain to fight against this food- borne pathogen.

Anti-Microbial Activity of GSE

In this study the effect of GSE (Vitisvinifera) has been evaluated against two most important bacterial strains in dental pathologies. A. actinomycetemcomitans was first identified as a possible periodontal pathogen in 1975 in localized aggressive periodontitis (LAP) and it's highly association with periodontal disease in adolescents has been established (63). On the other hand S. mutans is the primary causal agent for dental caries specially in the initiation and development stages (64), this microbe was first described in 1924 (65). Grape (Vitisvinifera) seeds are considered rich sources of polyphenolic compounds, mainly monomeric catechin and epicatechin, gallic acid and polymeric and oligomericprocyanidins (66). Grape phenolics are simple molecules, such as hydroquinone, pyrocatechol, caffeic acid, ferulic acid, p-coumaric acid, gallic acid, ellagic acid and resveratrol [10]. Furthermore, GSE is a rich source of diverse bioflavonoids, collectively known as grape seedproanthocyanidins extract (67). Polyphenols are well documented to have microbicidal activities against a huge number of pathogenic bacteria (68,69). The mechanism of polyphenols toxicity against microbes may be related to inhibition of hydrolytic enzymes (proteases and carbohydrolases) or other interactions to inactive microbial adhesions, cell envelope transport proteins and non specific interactions with carbohydrates (68). It means that phenolic antibacterial activity is due to enzyme inhibition by the oxidized compounds possibly through a reaction with sulfhydryl groups or through more non specific interactions with the proteins (68,70), further more flavonoids and tannins can bind or form precipitates with various proteins (71).At all with consideration of inhibitory effect of GSE on A. actinomycetemcomitans, it may have potential for further development as natural agent in prevention of periodontal disease. Further studies with different species of S.mutans and different concentration of GSE are recommended. Grape seed extract as a natural antimicrobial compound derived from Vitisvinifera has inhibition effect against A. actinomycetemcomitans ATCC 43718. There was not any bactericidal or bacteriostatic effect observed against S. mutans PTCC 1683.

Conclusion

Thereby this review article compiles all works done using grape seed extract that is potentially beneficial in application during dental procedures. Hence, this helps other investigators to further develop other methodologies using grape seed extract that is more effective than the present artificial products available that in the long run may affect the oral cavity.

Abstract

The most common cause of dental crowding is the presence of an arch-length--tooth-size discrepancy. Conventional methods of gaining space in orthodontics involve the extraction of teeth, often premolars. However, there are a number of clinical situations in which the extraction of permanent molars might be considered. The main aim of this review article is to know in detail about dental crowding.The objective of this article is to assess dental crowding in all aspects and to know the opinions of different authors.

The present study was to know about dental crowding in detail. Various articles from different authors were collected and summed up as a review article so that dental crowding is knownelaborately in all aspects. Dental crowding is defined as a discrepancy between tooth size and jaw size that results in a mal alignment of the toot. Some reasons for dental crowding could be excessively large teeth, small jaws, and a combination of both. The main causes for dental crowding are Mesio distal width of the teeth is directly related to crowding in the arch. Arch length and arch width is inversely related to crowding. In isolation these parameters may sometimes not show a significant correlation. Together arch length and tooth size are the major cause of crowding in dental arches. Orthodontic treatment of dental irregularity and crowding is achieved by either expanding the dental arches or creating space through tooth extraction or enamel stripping or a combination of any of these alignment with orthodontic appliances.

Key Words: *Dental crowding, primary crowding, secondary crowding, tertiary crowding, relapse, supracrestalfibrotomy.*

Introduction

Dental crowding is defined as a discrepancy between tooth size and jaw size that results in a mal alignment of the toot. Some reasons for dental crowding could be excessively large teeth, small jaws, and a combination of both when teeth become crowded it is due to lack of space for all of the teeth to properly fit. Crowding of teeth occurs when the tooth and jaw size do not have a harmonious relationship. Early or late loss of deciduous teeth and improper tooth eruption can also cause crowding. [(1)]

Dental crowding is distinguished into 3 types:

1) Primary crowding
2) Secondary crowding
3) Tertiary crowding

Primary crowding refers to the crowding caused by the genetically determined size discrepancy between the teeth and the jaw that contains them.

Secondary crowding is the shortage of space that can manifest after extraction of deciduous teeth through migration of neighbouring teeth in to the open space. It also includes crowding caused by deviating functional conditions.

Tertiary crowding refers to irregularities developing in the mandibular and sometimes slightly in the maxillary anterior region during early adulthood and later[(2)].

The accurate assessment of crowding is an essential part of orthodontic diagnosis and subsequent treatment planning and may be affected by a number of factors. The principal factors are the mesio-distal tooth widths and arch length. Other factors can include arch form, arch symmetry, and curves of Spee, the correction of which may require, or sometimes create space and therefore affect the assessment of crowding [(1)].

In an attempt to more accurately quantify the effects of these different factors, a number of formal space analyses have been developed [(2-7)],the most popular probably being the Royal London Space analysis [(8,9)]. The purported benefits of such analyses include consistency in treatment planning and as an aid for trainee orthodontists when assessing space requirements.The

most common cause of dental crowding is the presence of an arch-length--tooth-size discrepancy. Conventional methods of gaining space in orthodontics involve the extraction of teeth, often premolars.

However, there are a number of clinical situations in which the extraction of permanent molars might be considered. One of the greatest writer in Spanish language and one of the world's greatest novelists Miguel de Cervantes Saavedra, said that "Every tooth in a man's head is more valuable than a diamond". The statement is quite true because teeth are the most enriching or most beautifying segment of the face and yearning for teeth, which give in any event the presence of perfection. Any irregularity or imperfection such as dental crowding in the teeth can change one's beauty, which is undesirable. In this regard the orthodontic treatment plays an important role.

Dental crowding, also referred as swarming, can be characterised as an inconsistency between tooth size and arch dimension which results in malocclusion. Dental crowding occurs because of the absence of coordination between the tooth size and arch dimensions and results in positioning the teeth on each other. When there is shortage of space for the arrangement of teeth in the dental arch, teeth experience the ill effects of rotation dislocated eruption etc., [(28)]

Crowded teeth are very difficult to clean properly and thoroughly, which results in poor mouth cleanliness and further dental and medical problems. Mesiodistal crown Diameter (MD) which is also known as tooth size, tooth crown size, or tooth width, in human populations has been used in various studies due to its role in human advancement and biological problems as well in forensic investigations and clinical dentistry.

Various factors are responsible for dental crowding, including the effect of the environmental as well as genetic factors, on dental arch dimensions such as arch width, arch length, arch perimeter etc. Mesiodistal tooth width is additionally influenced by hereditary qualities, race, and sex [(28)]. However, the reasons for overcrowding have not completely been comprehended till now [(29)]. The factors that may contribute to teeth crowding are broad teeth, bony bases and also the developmental pattern towards a decreased facial skeletal size without a relating diminish in tooth size [(30)]. Crowding and spacing can be depicted as a declaration of an adjusted proportion

between tooth size and dental arch dimensions, both of which are affected by inherent and ecological components [31]. The arrangement of teeth inside the upper and lower arch, for the most part, relies on the relationship between tooth size and jaw size. Any irregularity amongst dental parameters, for example, tooths size and arch dimension have been studied by several investigators [32].

The advanced medical imaging like Computed Tomography (CT) scan provides cross-sectional images of internal body structures [33]. A 3D CT can generate the volume data with high-quality images, permits estimation or measurement of structures to be made on a picture helping analysis and diagnosis [34].

Multi-Detector Computed Tomography (MDCT) can give more geometric accuracy than other devices such as cone beam computed tomography and Vernier's calliper [35]. Measurement of orthodontic outcomes only in the sagittal view, as recorded in 2D lateral cephalograms or profile photographs may not be sufficiently informative, but the 3D CT gives better frontal and three-quarter profile data for diagnosis, treatment planning, and measurement purposes [35].

The main aim of this review article is to know in detail about dental crowding.The objective of this article is to assess dental crowding in all aspects and to know the opinions of different authors.

Materials and Methods

The present study was to know about dental crowding in detail. Various articles from different authors were collected and summed up as a review article so that dental crowding is known elaborately in all aspects. The articles were collected by manual searching of the references of the relevant retrieved articles, peer-reviewed orthodontic journals, and gray literature. Search terms included dental crowding, orthodontics, and aesthetics. Non-English articles were excluded from the review in the study-selection stage. Data extraction and evaluation of primary studies were performed independently by 2 reviewers.

Discussion

Crowding of teeth is considered as the most common type of malocclusion. Dental crowding can be defined as a disparity in the relationship between the tooth size and jaw size which result in

the imbrications and rotation of teeth. Tooth size-arch length discrepancy (TSALD) is a well defined means of assessing dental crowding[16]

The face is said to be the most important physical characteristic in the development of self-image and self-esteem, as positive social interactions have been shown to result in better interpersonal relationships and more self-confidence[39,40]. Any significant deviations from the norm may result in feelings of insecurity related to appearance, inhibition in social contacts, and comparison of self with others considered to be 'superior', all of which may negatively affect the quality of life of the individual[41].

Malocclusion is a causative problem in a lot of dental diseases so its documentation will help create awareness among the public [42]. The perception of aesthetics varies from person-to-person and is influenced by personal experiences and social environment [43]. The primary dentition is an important indicator of the permanent dentition. Absence of spaces in the primary dentition indicates that some malocclusion might appear in the future permanent dentition [44]. Third molar eruption is a very important clinical issue because retention of this tooth might be beneficial for orthodontic anchorage, prosthetic abutment or transplantation [45].

Ever since Gregor Johan Mendel proposed the law of inheritance, genetics has transcended the field of health and has entered all walks of life in its application. Thus, the gene is the pivoting factor for all happenings revolving around it [46]. This indicates that gene acts as a significant factor in dental crowding.

Relapse is the loss of any correction achieved by orthodontic treatment. The technique to prevent relapse requires the use of fixed retainers in both arches. It also seems important the use multi stranded wires, coaxial type, made of stainless steel with 0.021mm in diameter due to the excellent stability and surface roughness which allows the wire to hold the elastomeric solid thread that will generate the necessary force to move the teeth. [10].

Nance[11] described dental crowding as the difference between the space needed in the dental arch and the space available in that arch, that is the space discrepancy. Thus, crowding or spacing can be described as an expression of an altered tooth tissue ratio or as a dentoalveolardisproportion. Many investigators have examined the relationship of arch size, and tooth size with crowding. The observations made in these studies are quite conflicting.

Lundstorm[12]and Fastlicht[13]found on one hand, a significant relationship of dental crowding with tooth size, whereas Mills[14] and Howe [15] found a more significant relationship of dental crowding with arch dimensions.

Although, previous studies have compared the tooth size between dental arches with or without crowding in some specific ethnic group, so far no such studies have been done on the population. One of the most common malocclusions facing the orthodontist is the crowding of the teeth before as well as after the completion of orthodontic treatment. The current emphasis on non extraction therapies has result in significant reduction in number of teeth extracted for the orthodontic treatment.

The relationship between dental crowding and different dental parameters such as tooth size and arch dimension has been studied in great detail by investigators such as LundstromA -1951and Mills -1964[17-20]. The finding of this study partially agreed to Fastlischt J -1970 finding showed a significant relationship between crowding and mesiodistal width of incisor. The difference in the mean values collective of mesiodistal tooth between the crowded and the non crowded group was found to be not statistically significant in agreement with Waheed -Ul- Hameed -2005[21-25]

Gilmore CA, Little RM -1984 findings showed that there is a weak correlation between mesiodistal width of incisors and irregular alignment of teeth over long term study but previous authors have suggested that well aligned mandibular incisor are narrower mesiodistally than incisors which are crowded[26,27].

Stability of Crowding

It is also called the “stabilisation” or “retention period”. The orthodontic retention phase also called orthodontic contention is aimed at minimising unwanted dental movements and maintaining the corrections obtained during the initial period following the removal of brackets or other appliances used for correction[20]. Even if the most critical period is the first few months and year following the end of treatment, it is often indicated to stabilise or retain the teeth for a much longer period. Certain practitioners even advocate “lifetime” retention.

Circumferential Supra Crestal Fibrotomy

Supra crestal fiberotomy is the procedure done to prevent relapse of the rotated tooth after the orthodontic procedure. It severes the attachment of supra-alveolar and transseptal fibers around the tooth[36].Reitan, in 1969, showed that the relapse of the rotated tooth will occur 5 hours after removal of the appliance[37]. So, the circumferential supracrestalfiberotomy (CSF) procedure should be carried out toward the end of finishing stage of active orthodontic treatment. The continuous use of CSF in orthodontic forced eruption for crown lengthening prevents the coronal displacement of gingiva and the attachment apparatus. This prevents the additional need for gingival recontouring after orthodontic treatment. Repositioning of the rotated teeth is often easier during orthodontic procedures but poses a problem in retaining its new position in the arch. The reorganization of the periodontal fiber complexes, transseptal fibers, and the supra-alveolar fibers occur after orthodontic tooth movement.

Transseptal fibers stretch elastically during orthodontic treatment and tend to pull the teeth back toward their original position. Campbell, in 1975, stated that the supra-alveolar fibers are non-elastic by nature and more stable with a slower rate of turnover. These fibers do not adapt to new tooth positions and are in part responsible for relapse after the active orthodontic treatment procedures. Transseptal fibers, sharpey's fibers of the newly formed bone may rearrange even after a retention period of 4-6 months[37].

Therefore, the retention period should continue for a 12-month period[38]. The fibrotomy or the pericision in the orthodontic surgical procedure designed to sever the gingival fibres around the tooth. It usually reduces the tendency to relapse of tooth rotations corrected by dental braces or other treatments. The most frequently encountered post orthodontic problem is the retention of re-established tooth position. Relapse (drifting of the tooth back to its position prior to orthodontic correction) may occur anywhere, but it is often associated with teeth that have undergone rotation (twisting) as a part of the orthodontic therapy[21,22].

It involves the detachment of fibres that attach he tooth to the bone via the gum. It acts much like a twisted rubber bands and releasing the tension between the fivers and the tooth and reduces the forces that attempt to pull the tooth back to its original position. It is shown to be effective in

preventing the relapse of the teeth. It is a procedure that is painless as long as the patient takes an analgesic after the numbing has worn off.

Plaque Check

Dental crowding is not just a cosmetic flaw. Dental crowding is sure to give gingival and other periodontal tissue problems. Crowded and misplaced teeth are particularly vulnerable to decay due to constant plaque accumulation. This is a vicious circle where plaque causes tooth decay and inflammation of the gums due to dental crowding[(24)]. This circle can be broken by plaque check and orthodontic treatment which usually involves braces.

Treatment

Orthodontic treatment of dental irregularity and crowding is achieved by either expanding the dental arches or creating space through tooth extraction or enamel stripping or a combination of any of these alignments with orthodontic appliances.

Conclusion

Dental crowding is defined as a discrepancy between tooth size and jaw size that results in a mal alignment of the toot. Some reasons for dental crowding could be excessively large teeth, small jaws, and a combination of both. The main causes for dental crowding are Mesio distal width of the teeth is directly related to crowding in the arch. Arch length and arch width is inversely related to crowding. In isolation these parameters may sometimes not show a significant correlation. Together arch length and tooth size are the major cause of crowding in dental arches. Orthodontic treatment of dental irregularity and crowding is achieved by either expanding the dental arches or creating space through tooth extraction or enamel stripping or a combination of any of these alignments with orthodontic appliances.

Abstract

Stem cells have the potential to self-renew and to give rise to a variety of cell types that ensure tissue repair and regeneration throughout life. Dental pulp stem cells (DPSCs) are having a MSCs phenotype and they are differentiated intoneurone,cardiomyocytes,chondrocytes, osteoblasts and adipocytes. These cells have been isolated from dental and periodontal tissues, characterised, and tested for their potential applications in regenerative dentistry.It is done to educate the dentists and patient regarding the importance of stem cells in regenerative therapy.

Key Words: *Dental stem cells, differentiation, proliferation, scaffold,regeneration*

Introduction

Stem cells are immature, unspecialised cells that have the potential to develop into many different cell lineages via differentiation.There are two primary sources of stem cells:embryonic stem cells and adult stem cells. While there has been a debate on ethical issues surrounding the use of embryonic stem cells , adult stem cells are free of this controversy and only adult stem cells ,to date have been used to treat people(1,2).The most common source of adult stem cell is bone marrow, which contains both hematopoietic stem cells(also found in cord blood) and mesenchymal stem cells(also found in teeth).Bone marrow is a rich source of MSCs, which plays an important role in modern regenerative medicine(3). It is isolated in high number from cultures of bone marrow by selecting the cells that are adhered to tissue culture plastic and proliferates rapidly(4).

It is known that adult stem cells taken from one area of body can be transplanted into another area and grown into a completely different type of tissue. Dental stem cells are being studied for wide range of diseases due to their ability to form connective tissue , neural , bone ,muscle and dental tissues. Dental stem cells are present in various dental tissues including both deciduous and permanent teeth. The various sources of tissue in the oral cavity from where stem cells can be isolated are periodontal ligament, apical papilla, alveolar bone, dental pulp tissue, maxillary sinus, periodontal ligament granulation tissue and gingiva(5).

Regenerative capacity of the dental pulp is well-known and has been recently attributed to function of dental stem cells. Dental stem cells offer a very promising therapeutic approach to restore structural defects.Periodontal ligament- derived stem cells are able to generate periodontal ligament and cementum. Extracted third molars; exfoliating/extracted deciduous teeth; and teeth extracted for orthodontic treatment, trauma or periodontal disease are all sources of dental stem cells from the dental pulp. The dental pulp provides a scaffold of stem cells postnatallywhich is available, with a less invasive process thatmay results in minimal trauma(6,7).

Stem cells from deciduous teeth have been found to grow more rapidly than those from other sources, and it is believed that this is because they may be less mature than other stem cells found in the body(8).Additional advantages of sourcing stem cells from exfoliating deciduous teeth are that the cells are readily available, provided they are stored until they may be needed later in life; the process does not require a patient to sacrifice a tooth to source the stem cells; and there is little or no trauma(9).

Types of Dental Stem Cells

During formation of tooth,interactions between dental papilla and epithelial cells induce tooth morphogenesis by promoting the subpopulation of mesenchymal cells to differentiate into odontoblasts,that results in formation of primary dentin(10,11).Theseodontoblast are believed to come from proliferation and differentiation of earlier population, which is present within pulp tissue.

The various groups of postnatal mesenchymal stem cells have been realised to produced from odontoblast like cells:-

- Dental pulp stem cells (DPSC)
- Stem cells of apical papilla (SCAP)
- Dental follicle progenitor cell (DFPC)
- Stem cells of human exfoliated deciduous teeth (SHED)

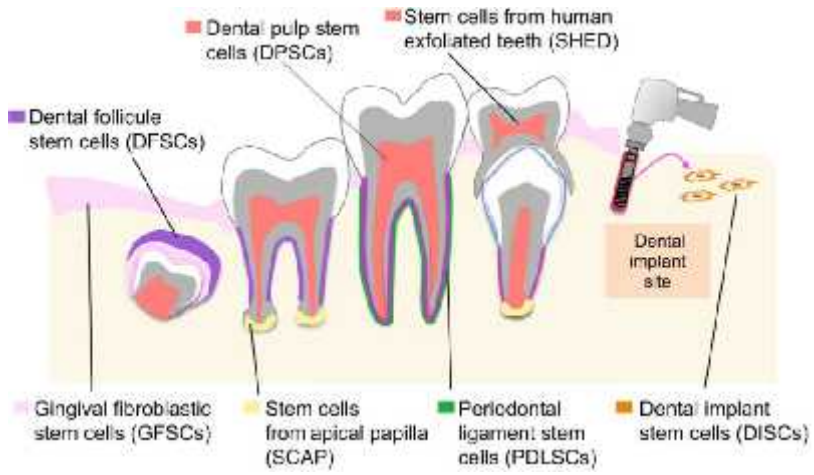

Figure 1: Types of Dental Stem Cells

Dental Pulp Stem Cells

Regenerative capacity of the dental pulp is well-known and has been recently attributed to function of dental stem cells. Dental stem cells offer a very promising therapeutic approach to restore structural defects.Periodontal ligament- derived stem cells are able to generate periodontal ligament and cementum.Extracted third molars; exfoliating/extracted deciduous

teeth; and teeth extracted for orthodontic treatment, trauma or periodontal disease are all sources of dental stem cells from the dental pulp. The dental pulp provides a scaffold of stem cells postnatallywhich is available, with a less invasive process that results in minimal trauma(12).

Johnsen in 1985 proved that DPSCs are capable of producing dental tissues in vivo including dentin , pulp and crown like structures(13).Whereas other investigations has shown that these stem cells can bring about formation of bone liketissues.

Stem Cells of Human Exfoliated Deciduous Teeth

They contain multi-potentstem cells from human exfoliated deciduous teeth(SHED) . They were identified to be a population of highly proliferative, clonogenic cells capable of differentiating into variety of cell types including neural cells, adipocytes and odontoblasts(14).Thus, the exfoliated deciduous teeth is aunique resource for stem cell therapies including autologous stem cell transplantation and tissue engineering.

Stem Cells of Apical Papilla

A unique population of dental stem cells known as stem cells from apical papilla is located at the tip of growing tooth roots. The apical papilla is present only during root formation before the he tooth erupts into oral cavity. They have the ability to differentiate into odontoblasts and adipocytes. They contain larger number of adult stem cells than mature dental pulp. Thus, have a larger potential for regenerating dentin than dental pulp stem cells(15).

Dental Follicle Progenitor Cells

The dental follicle is an ectomesenchymeoriginated from connective tissue sac surrounding the enamel organ and dental papilla of the developing tooth germ before eruption. It is believed to contain precursors or cementoblasts, periodontal ligament and osteoblasts(15).Dental follicle cells form periodontal ligament by differentiating into periodontal ligament fibroblasts that secretes collagen and interact with fibres on the surface of adjacent bone and cementum.

Therapeutic Potential

- **Dental Tissue Repair**

Stem cells have the potency to become an important tool of tissue engineering and regenerative medicine(16).Tissue engineering is utilising the principles of engineering and bioscience aiming to develop biological substances for the restoration, conservation and/or improvement of the tissue function(17). These include obvious uses of cells to repair damaged tooth tissues such as dentin, periodontal ligament and dental pulp. The tissue engineering using enamel and dental stem cell has been recommended as source of cells to facilitate repair of non-dental tissues such as bones and nerves(18).

- **Periodontal Regeneration**

The periodontium is a set of specialised tissues that surround and support to maintain them in the jaw. Periodontitis is an inflammatory disease that affects the periodontium and results in irreversible loss of connective tissue attachment and supporting alveolar bone(18).The challenge for cell based replacement of a functional periodontium is therefore to form a new ligament and bone, and to form ensure appropriate connections are made between these tissues as well as between bone and tooth root(19,20,21).The aim of current research is to use various populations of dental stem cells to replicate events in periodontal tooth development both temporarily and spatially, so that the healing can occur in a sequential manner to regenerate periodontium.

- **Regeneration Of Dental Pulp In Immature Tooth**

Dental pulp needs to be removed when it becomes infected, and this is complicated for root pulp that requires root canal treatment. The restoration of tooth pulp is thus a much sought after goal in dentistrybecause the current practice of replacing infected pulp with inorganic materials results in devitalised tooth. A recent studies have evaluated the de novo regeneration of dental pulp in emptied root canal space using dental stem cells(22,23).

- **Craniofacial Reconstruction**

Stem cells have been used in the tissue engineering of a human-shaped temporomandibular joint. Studies used MSC-derived cells encapsulated in a poly {ethylene glycol} diacrylate hydrogel that was moulded into an adult human mandibular condyle in stratified yet integrated layers of cartilage and bone(24).The osteochondral grafts, in the shape of human TMJs, were implanted in immunodeficient mice for up to 12 weeks. Upon harvest, the tissue-engineered mandibular joint condyles retained their shape and dimensions.Reconstruction of

craniofacial and dental defects using MSC avoids many of the limitations of both auto- and allografting techniques(25,26).Clinical studies are being conducted using stem cells for alveolar ridge augmentation and long-bone defects. Vascularised bone grafts are also used in development using stem cells, and reconstruction of a patient's resected mandible has been carried out using this technique.

- **Use Of Non-Dental Stem Cells**

The method for growing teeth from stem cells obtained in urine were identified. In this study, pluripotent stem cells derived from human urine were induced to generate tooth-like structures in a group of mice with a success rates of up to 30%(27). The generated teeth had features resembling that of normal human teeth except hardness (about one-third less in hardness of human teeth). The advantages were being noninvasive technique, low cost, and use of somatic cells (instead of embryonic) that are wasted anyways(28).The urine-derived stem cells doesnotnotproducetumourswhen it gets transplanted in the body unlike other stem cells; the autologous source of these cells reduces the likelihood of rejection.

- **Uses of Dental Stem Cells in Medicine**

Dental stem cells have the potential to be utilised for medical applications like heart therapies,regenerating brain tissue,for muscular dystrophy therapies and for bone regeneration(28).SHED can be used to generate cartilage as well as adipose tissue.In 2008 first advanced animal study for bone grafting was announced resulting in reconstruction of large size cranial bone defects in rats with human DPSCs(29).

Advantages

- Hematopoietic stem cells save thousands and thousands of patients each and every year. They are patients with cancer and several rare blood diseases.
- Stem cell research provides development in currently untreatable diseases like Parkinson's, Alzheimer's, cancer, osteoarthritis etc(30).
- Most scientists believe that stem cells are the key to one day grow tissues, organs and perhaps limbs. Researchers have already grown and transplanted simple organs, using a combination of stem cells and scaffolds.

- Stem cells have shown some very promising results in people with spinal cord injuries.
- Not all stem cells require the destruction (or killing if you prefer) of a human embryo. Adult and induced pluripotent stem cell lines can be developed using a piece skin or a bone marrow sample.
- Unlike embryonic, adult and induced pluripotent stem cells are autologous which means those that that developed from the patient himself. So, there is no risk of rejection for stem cell based treatments.
- The knowledge gained from stem cells providesus a better understanding of ageing.

Disadvantages

- The use of human embryonic stem cells requires the destruction of laboratory-fertilised human eggs. Many view the blastocysts destroyed during the process as just a mass of cells, while believe that life begins at conception and thus consider the whole process to be immoral and unacceptable.
- The embryonic and induced pluripotent stem cells have a potency to form tumours. The adult stem cells don't seem to have this problem, due to their limited differentiation nature.
- We must wait for years, perhaps decades before seeing widespread clinical application of stem cell therapies, with the exception of course hematopoietic stem cell transplantation.
- Having an experimental, none FDA approved treatment is dangerous and may prove to be deadly. This of course applies to many of the experimental, not FDA approved stem cell therapies provided all over the world by clinics and individual physician.

Conclusion

Stem cell-based therapies represent the most promising alternative for successful regeneration of damaged or pathological dental tissues or even the entire tooth following tooth loss. It is therefore essential to understand the mechanisms underlying the potential of the various dental stem cell populations as well as their behaviour after transplantation in ectopic sites.

Innervation and vascularisation play fundamental roles in the regulation of stem cell niches homeostasis, thus affecting the fate and behaviour of stem cells. Stem cell-based approaches are beginning to emerge in dentistry, and huge challenges and problems such the enamel and entire tooth regeneration should be overcome. Nevertheless, stem cell-based regenerative approaches are the future of dentistry that will benefit millions of patients worldwide.

Abstract

Para nasal sinuses comprises of four paired air-filled spaces which surrounds the nasal cavity, maxillary sinuses, above the eyes, frontal sinuses, between the eyes, ethmoidal sinuses, and behind the ethmoids, sphenoid sinuses. The sinuses are named based on the front facial bones in which they are located. The maxillary sinus is pyramid shaped and is the largest of the four paranasal sinuses. The article talks about the development of maxillary sinus and the dental surgeries that it is involved in.

Key Words: *Maxillary sinus, maxillary sinus grafting, maxillary sinusitis*

Introduction

The maxillary sinus was described firstand properly shown by Leonardo da Vinci, but the earliest significant discovery was by Nathaniel Highmore, the British surgeon and anatomist who had discussed the maxillary sinus in detail in 1651. It is found to be present during birth as minor air spaces and develops throughout life.

The paranasal sinuses develop within the bones of the viscerocranium. The maxillary sinus is the first paranasal sinus to form [1]. The development of the maxillary sinus has been documented as early as the 17th week of the prenatal period [2], however it is after birth that the majority of growth occurs. In new born children the viscerocranium is relatively undeveloped. It grows simultaneously with other bones and reaches 25% of its final size by the end of the 2 years and up to the 50% by the end of the 8th year of age. It was reported, that the growth of the viscerocranium is most extensive in the vertical direction, slower in the anterior andposterior direction, and slowest in the horizontal direction [3]. As the paranasal sinuses are mostly enclosed within the bones of the viscerocranium, the dynamics of the development of the skull should also refer to their growth. Interestingly, Scuderi et al[1].

stated, that at birth, the rudimentary aerated maxillary sinus is 6–8 cm^3 in volume with its maximal dimension in the anterior andposterior direction. Bone expansion during the formation of the paranasal sinuses although continuous, is not uniform and can take place at different times and at different speeds within the developmental process. Therefore, the shape and size of the paranasal sinuses are probably the most variable of all the anatomical structures of the body. Due to extended aeration, the walls of the paranasal sinuses may turn into thin bony laminae. Undoubtedly the shape and size of the maxillary sinus is determined but not limited by the boundaries of surrounding bony structures. A close link between the size of the facial skeleton and the maxillary sinus volume is suggested, even when severe facial pathologies are present [3]. As the shape and size of the maxillary sinus reflect the development of bony structures, it may be associated with determining the shape of the middle face, moreover, it is suggested that the maxillary sinus might play a crucial role in the formation of facial contours [4]. Despite many proposed theories, the real function of the maxillary sinuses has not been clarified [5]. The most often believed is that the sinuses support the respiratory function and resonation, but, it cannot be excluded, that they arose as an aid to the skull structure or are residual remnants with yet unknown purpose [6]. According to Kawarai et al, [7] the fact, that the paranasal sinuses constitute the major cavity of the skull indicates thatthe particularity ofthe sinus is their air space. Nonetheless,the aeration of the sinuses must play an important role if the maxillary sinus is already filled with air in newborns [8,9]. Therefore, it is suggested that the volume of the air cavity is the simplest and most important index for sinus evaluation

The maxillary sinus is a variable anatomical structure as show in a study done on the 3D reconstruction and simulation of the maxillary sinus showed that its morphology and size are variable. Also, the developmental pattern of the paranasal sinuses varies widely according to the individual and the age [11].

Anatomical and developmental descriptions of the maxillary sinus may be of great clinical importance. The pneumatization of children’s sinuses and the pattern of normal development may serve as a reference for evaluating normal or abnormal development of the maxillary sinus. Normal values and clinical indexes can be used in diagnostic, preoperative evaluation, and treatment planning. More studies on the dimensional changes in the maxillary sinus during growth and volume of the normal maxillary sinus may help in radiological interpretation of the status of the maxillary sinus and its possible pathologies.

Sinus means “pocket” in Latin. Human beings have airfilled spaces that are found surrounding the nasal region known as the paranasal sinuses. These paranasal sinuses are paired and they are four in numberincluding the front sinus, ethmoidal sinus, sphenoidal sinus and the maxillary sinus. The largest of the four paranasal sinuses is the maxillary sinus. Although insufficient literature is available some studies show that the roles of these sinuses include decreasing the relative weight of skull, increasing voice resonance, providing a buffer against blows to face, insulating structures, and humidifying/heating inhaled air[12].

The membrane that lines the walls of the maxillary sinus is called Schneiderian membrane. It is multi-layered and 0.13 mm to 0.5 mm in thickness. The condition of the maxillary sinus is self-maintainingby postural drainage and with the help of the ciliated epithelial lining, which places the bacteria towards that of the ostium. This ostium is described as a non-physiologic drainage port high on the medial wall that opens into the nasal cavity between the middle and lower nasal conchae (hiatus semilunaris).

Sinus lifting procedures may help in the improvement of the symptoms of sinusitis and congestion by relocation of the sinus lining closer to the drainage port, and this does not affect the normal physiological function of the maxillary sinus [12].

Traditionally, the maxillary sinus has been an area that has been avoided in most dental procedures. In the past general practitioners and oral maxillofacial surgeons have avoided entering the maxillary sinus from the oral cavity unless they considered it to be absolutely necessary[13]. The maxillary sinus is pyramidal in shape. The base of the pyramid is the medial wall of the sinus that is also the lateral wall of the nasal cavity, and its apex is pointed toward the zygomatic bone. The roof of the sinus is also the floor of the orbit. The average volume of a sinus is about 15 ml (range between 4.5 and 35.2 ml). The maxillary sinus does not fluctuate in its size and maintains itself while the posterior teeth remain in contact as the size increases with age. This is a process commonly known as pneumatisationand is usually occurring due to atrophy caused from reduced occlusal function[14]. The pneumatisation of this sinus is variable and ranging from agenesis to hyperpneumatization.

Until the age of 8 the maxillary sinus grows 2 mm a year vertically and 3 mm a year in an anteriorposterior direction. There are spurts of maxillary sinus growth from birth to 2 years, from 7 and a half to 10 years, and from 10 to 12 years of age. There is slower steady growth

until 14 to 18 years of age. From 7 months to birth, the sinus averages 7 mm to 16 mm anteriorposterior and 2 to 13 mm superiorinferior and 1 mm to 7 mm [15].

The blood supply to the maxillary sinus is derived primarily from the maxillary artery. The posterior superior alveolar and infraorbital arteries anastomose in the bony lateral wall. On average, the anastomoses intraosseously arises mostly in 100% of the cases and usually from a height of 19mm from the crest of the alveolar ride, however anastomoses extraosseously arises mostly in about 40% of the cases and this is seen to be at a height of 23 mm from the crest of the alveolar ridge. More than one septa can be involved in division of the maxillary sinuses, known as Underwood's septa [16,18].It is observed in about 30% of cases and most dominant in anterior region (commonly seen in between the 2^{nd}premolar and 1^{st}molar) observed in 77% of the cases. The mean height of the septae is 7.9 mm (range 0 to 17 mm). [16,18.]

Contents

Development

The maxillary sinuses are the only pair of sinuses of the paranasal sinuses which are visible during the time of birth. During the time of birth they have the size of a small lima bean measuring about 8x4 mm, and are situated with their longer dimension directed anteriorly and posteriorly.They develop at the third month of intrauterine life, in the place existing between the oral cavity and the floor of the orbit.They develop as evagination of the mucous membrane of the lateral wall of the nasal cavity at the level of the middle nasal meatus forming a minute space that enlargesin the inferior directioninto the maxillary sinus region [15].The maxillary sinus enlarges variably and greatly by pneumatisation (the formation of air cavities in tissues) until it reaches the adult size by the eruption of the permanent teeth [15].Growth of the sinus slows down with decline of facial growth during puberty but continues throughout life.

Function of Maxillary Sinus

- Lightening the weight of the skull.
- Resonance of voice.

- Regulations of the Olfactory and respiratory modulations through the air pressure within the sinus during respiration.
- Inspired air conditioning.
- Craniofacial protection against mechanical trauma.
- Bactericidal enzyme production (lysozyme) has the significance in protection against bacterial infection of the nasal mucosa.

Anatomy of Maxillary Sinus

There are not only variations in size, shape and position among different individuals, but also there is difference in different sides of the same individual.which is pyramidal in shape that has a base, an apex and four walls.

- The base: lateral wall of the nasal cavity.
- The apex is directed laterally towards the zygomatic process of the maxilla.
- The four walls:

  Anterior wall: Frontal surface of the maxilla.

Posterior wall: Infratemporal surface of the maxilla.

Roof: Floor of the orbit.

Floor: Alveolar process of the maxilla.

- Maxillary sinus is seen to have a direct communication with the middle meatus and this commonly described as ostiummaxillaewhich is about 36 mm in its diameter.
- The sinus has septa that partially divide it into intercommunicating compartments with separate ostia.
- The average capacity of the maxillary sinus is about 15 ml. and its average dimensions in centimetres are transversely 2.3cm, anteroposteriorly 3.4cm, vertically 3.35cm.

Development Anomalies of Maxillary Sinus

Agenesis (imperfect development or complete absence), Aplasia and Hypoplasia (altered development or under development) of the sinus occurs either alone or in association with other anomalies like:

- Chronal atresia
- Cleft palate
- Septal deformity
- Absence of concha
- Malformation of external nose

- Maxillary sinus hypoplasia is the name given by dentists to define the underdevelopment of the maxillary sinus. It can be detected radiologically and can be related to maxillary sinusitis.
- Maxillary agenesis refers to the complete absence of the maxillary sinus surrounding the nasal cavities.
- Maxillary aplasia is the failure in the development of the maxillary sinus.

Occurrence of any of these three scenarios could lead to the anomalies mentioned above.

Maxillary Sinusitis

Sinusitis is a common disease seen to affect approximately 35 million people per year in the region of North America. An approximate amount of two to three billion dollars is paid for health treatment per year. Nevertheless, maxillary sinus infections are on the most missed out diagnosis seen in clinical practice and it is a real problem. The dental practitioner must be fully aware of the possible symptoms and representation of maxillary sinusitis in order to diagnose it correctly. In dental practice sinusitis of both acute and chronic type may represent itself as a chronic orofacial pain or atypical odontalgia and will be in need for proper medical care. Odontogenic origin for sinusitis is generally a well-recognizedwith an incidence of around ten percent. These cases of sinusitis of odontogenic originwhich appearsthat are usually resistant to conventional treatment methods should be prescribed proper medications

and referral. To ensure thatproper care for a patient presenting with maxillary sinusitis the dental practitioner must be well versed in the knowledge of maxillary sinusitis.

Maxillary sinusitis is inflammation of the maxillary sinuses. Themost commonly observed signs and symptoms of maxillary sinusitis are mild headache, usually near the region of the maxillary sinus and foul-smelling discharge, possibly with some systemic signs of infection such as fever and weakness. The skin over the involved sinus can be tender, hot, and even reddened due to the inflammatory process in the area. On radiographs, there is opacification (or cloudiness) of the usually translucent sinus due to retained mucus[19].

Maxillary sinusitis is common due to the close anatomic relation of the frontal sinus, anterior ethmoidal sinus and the maxillary teeth, allowing for easy spread of infection.The maxillary sinus may lead into the mouth through an abnormal opening, an oroantral fistula[14,15].

Microbiology of Maxillary Sinusitis

In health the paranasal sinuses were initially thought to be sterile. This is highly controversial as many studies have documented the presence of normal flora in these air-filled cavities[20]. Most cases of sinusitis are thought to be of bacterial etiology. The microbiology of sinusitis of both acute and chronic type is usually different can vary depending upon which sinus is involved. In sinusitis of odontogenic origin, it isoften the polymicrobial typewhich can be a mixedaerobic/anaerobic type in nature.

In sinusitis of acute type, Streptococcus pneumonia and Haemophilus influenzae have been identified as primary etiologic agents. A large number of organisms, including coagulase positive and negative Staphylococci and Escherichia coli have found to cause about 5% of maxillary sinusitis cases.

In sinusitis of chronic type, the etiologicorganisms can vary from type to type, with anaerobic organisms isolated generally with an increased frequency. Studies show that it has been reported that 88% of culture positive cases contained anaerobes, and 32% were part of a mixed infection [20]. Of the anaerobes approximately 50% exhibited beta lactamase activity. The predominant organisms include Bacteroides species, anaerobic cocci, Pepto streptococcus anacrobius, P. niger and Clostridium species.

In sinusitis caused by odontogenic origin, most were considered to be mixed aerobicand anaerobic infections with the most common organisms including anaerobic streptococci, Bacteroides, Proteus and coliform bacilli[21,22].Patients with cystic fibrosis and immotile cilia syndrome are predisposed to Pseudomonas aeruginosa and S. aureus infections.

Sinusitis Treatment

Traditionally the treatment of acute maxillary sinusitis is usually prescription of a broad-spectrum cephalosporin antibiotic resistant to betalactamase, administered for 10 days.

There areadvantages in the treatments that primarily focus on the underlying issue and probably inflict damage to the nasal membrane causing inflammation, instead of the secondary bacterial infection that has been the primary target of past treatments for the disease. Direct removal of mucus that is loaded with toxins from the inflammatory cells is the surgical procedure for the treatment of sinus with chronic infections. Leaving the mucus behind might predispose early recurrence of the chronic sinus infection.

Maxillary Sinus Floor Life Augmentation

Sinus lift procedure is a surgery increases the bone height in the upper jaw in the area of the teeth present within the maxillary sinus region. It is commonly also known as sinus augmentation. The bone is formulated between the jaw and the maxillary sinuses that is present on the either side of your nose. The sinus membrane has to be moved upward or lifted inorder to create room for the bone[23,24]. Maxillary sinus has great potential for healing and bone formation and indicates that bone grafts or bone substitutes may not be needed to achieve augmentation of the maxillary sinus floor[15].

A sinus lift usually is done by a specialist. This could be either an oral and maxillofacial surgeon or a periodontist. A sinus lift procedure is carried out when there is not enough bone height in the upper jaw, or the sinuses are too close to the jaw, for dental implants to be placed[23].

The gum tissue is raised, exposing the bone. A small oval window is opened in the bone. The sinus and the jaw are separated by a membrane lining the sinus on the other side of the window.This membrane is gently pushed up and away from your jaw[24].

Surgical Methods for Enhancement of the Alveolar Bone Height in the Posterior Maxilla

Maxillary Sinus Floor Augmentation Applying the Lateral Window Technique with a Grafting Material and Simultaneous or Delayed Implant Installation

Surgical intervention is one of the most commonlyemployed method to increases the vertical height of the crest of the alveolar ridge before or during implant placement to ensure success of the implant supported prosthesis and many cases have been reported and documented such as reviews and meta-analysis[20-25].

Surgical Technique

One of the methods to carry out maxillary sinus augmentation is the lateral window techniqueand it is usually performed under local anaesthesia or conscious sedation. Through the oral mucosa, access is gained to the maxillary sinus usually in the region of the anterior as well as the lateral wall of the maxillary sinus. A mid crestal incision is made along with vertical cuts in the anterior and posterior direction. Once this is done,a mucoperiosteal flap with a base shaped in a trapezoidal pattern is elevated allowing access to the lateral wall of the maxillary sinus[23]. An osteotomy cut is then performed on the lateral wall of the maxillary sinus with the use of burs and a high rpm handpiece avoiding any injury to the Schneiderian membrane. The osteotomy window and the Schneiderian membrane is cautiously improved from the floor of the maxillary sinus in addition to the lateral and medial sinus wall and displaced dorsocranially with blunt dissector to create a compartment for placement of the graft fabric. Implants are inserted simultaneously with the augmentation system if the height of the residual alveolar bone gives enough number one implant balance. An implant mattress is successively organized with burrs before the implant are inserted inside the residual alveolar bone with the implant tip exposed in the created compartment within the maxillary sinus. The graft cloth is densely packed across the exposed implant floor to facilitate de novo bone formation. The lateral window to the maxillary sinus is commonly protected by using a resorbable collagen membrane to prevent ingrowth of fibrous tissue earlierthan the mucoperiosteal is readapted and sutured. Once the stability is confirmed the procedure is carried out one year after the augmentation and the prosthetic replacement is initiated 3-6 months after the successful placement of the implant [23-26].

Surgical Complications

Perforation of the Schneiderian membrane is one of the most common surgical complication that can occur during the procedure of sinus floor augmentation.Presence of septa a residual crestal bone height of less than 3.5 mm increases the risk for a sinus membrane perforation. However, perforation of the Schneiderian membrane seems not to influence the final treatment outcome, but a higher prevalence for sinusitis is reported in cases of membrane perforation. Other complications include bleeding, migration of dental implants into the maxillary sinus, postoperative infection, sinusitis, exposure of the graft, graft loss, oedema, seroma formation, benign paroxysmal positional vertigo and exposure of the collagen membrane. Smokers generally exhibited greater chances for complications and a newly published systematic review concluded that smoking seems to be associated with increased risk of wound dehiscence and infection after maxillary sinus floor augmentation.

Conclusion

The dental practitioner must be well aware of the literature on the anatomy of the maxillary sinus in order to perform sinus procedures and successfully diagnose and treat maxillary sinusitis.

Abstract

Enamel defects occur primarily as developmental defects due to systemic problems that occur during pre and postnatal periods. The extent of the defect shows the passage of early developmental events or stresses. Early detection of these conditions during pregnancy stage helps in preventing the deleterious defects of the disease. A Pedodontists should be better informed as the affected children will visit them at an early age due to defect present and the severe morbidity can lead to improper dentition at an early age, also the complexity of the disease will affect the treatment plan for that individual.

Key Words: *Amelogenesisimperfecta, Developmental,Enamel defect, Hypoplasia, Primary, Pathogenesis*

Introduction

Amelogenesis or enamel formation is a programmed genetic mechanism, which can be affected due to environmental disturbances. The developmental defects once established cannot be repaired. Enamel formation occurs through the pre and postnatal life of a child and thus act as a storehouse of the environmental insults received during this process [1] [2]. This helps us detect the timing of the systemic insult [3]. These defects can be classified based on the type of dentition affected, the causative agent or the histopathology of the defect [4].

Pre term birth is associated with Hypoplasia of the primary dentition. Primary tooth Hypoplasia leads to various other deformities like increased caries risk, esthetic deformities and accelerated attrition of teeth, which results in loss of vertical dimension. The aim of this study is to educate the clinicians about this defect, which will help in better diagnosis and treatment of the individual [5].

Etio-pathogenesis

Various systemic and local factors are attributed for the developmental defects of enamel. Systemic factors include nutrition, hypoglycemia, hypocalcaemia, metabolic disorders, respiratory distress, sepsis and neurological disorders. The non-specific appearance of the defect makes it difficult to point the etiologic factor [6-9]. The local factors include injury to the taste buds; shorter period of breast feeding, early bottle-feeding and the general factors are socioeconomic status, low weight and height for the age [10][11].Neonatal lines are used as reference to estimate approximate timing and position of insult [12].

Clinical Features

The clinical presentation of the defect can vary from simple demarcated opacity to complete absence of enamel tissue. The primary feature of this defect is that they are multiple, symmetric and chronological in nature [13] [14]. The clinical manifestation can vary with type of etiologic agent, duration, calcification level and the metabolic activity of the individual [15].

The enamel defects also help the clinician to assess the presence of any other systemic disorder present in the patient such as brain injury [16], intelligence quotient, neurologic deficits [17] and renal disease [18].

The dental problems encountered due to this defect include poor esthetics, malocclusion and increased risk of dental caries. The presence of enamel Hypoplasia in primary teeth is also observed to be a predisposing factor for the occurrence of the defect in permanent dentition [19] [20]. The increased caries incidence can be due to more porosity in hypo calcified teeth, increased biofilm adherence that leads to higher number of Streptococcus mutans [21][22].

Treatment

The extent and severity of the lesions decide the ease of treatment required. The treatment aims at maintaining healthy teeth in oral cavity until the permanent teeth erupt. For esthetic corrections, adhesive restorations, polycarbide crown, strip crown and stainless steel crown are used. The unrestorable teeth are extracted and space maintainers are placed [23-26].

Amelogenesis Imperfecta

Amelogenesis imperfect is a developmental disorder that is genomic in origin, which produces biochemical and morphologic changes in the tooth structure. It can be expressed as autosomal recessive, autosomal dominant, sex linked, and sporadic cases or associated with another syndrome [27].

Classification and Etiology

Initially, they were classified as hypo plastic and hypo calcified types but with time they have been periodically classified under various other categories such as their appearance, mode of inheritance, genome and their biochemistry. However, the inheritance pattern is considered to be a more useful classification than the other factors considered [28] [29].

The formation of enamel is a very complex and organized process that occurs by the interaction of various organic molecules such as enamelin, amelogenin, ameloblastin, tuftelin, amelotin, dentin sialophosphoprotein and enzymes such as kallikrein 4 and matrix metalloprotease 20 [27]. The pattern of inheritance, which influences the phenotype of the disease, is seen in [Table 1].

Table 1: Type of AI Caused by Various Mutations

Genomic Site	Type Of Disease
AMELX, AIH I	X-Linked disease [30]
AIH3	X-Linked disease [31]
AIH2, ENAM 4q21	Autosomal dominant and recessive disease [32]
AMELOTIN 4q13	Can cause any type of disease [33]

Many authors under different categories have classified the condition. Some of these classifications are given below [27].**Weinmann et al, in 1954** Two types based on phenotype: hypo plastic and hypo calcified**Wit kop, 1988** Four major categories based on phenotype (hypo plastic, hypo maturation, hypo calcified, hypomaturation-hypoplastic with taurodontism) subdivided into 15 subtypes by phenotype and secondarily by mode of inheritance

Type l. Hypo plastic
Type lAHypo plastic, pitted autosomal dominant
Type lB Hypo plastic, local autosomal dominant
Type lCHypo plastic, pitted autosomal recessive
Type lDHypo plastic, smooth autosomal dominant
Type lEHypo plastic, smooth X-linked dominant
Type lFHypo plastic, rough autosomal dominant
Type lG Enamel agenesis, autosomal recessive
Type ll. Hypo maturation
Type llA Hypo maturation, pigmented autosomal recessive
Type llBHypo maturation, X-linked recessive
Type llCHypo maturation, snow- capped teeth, X-linked
Type llDHypo maturation, snow- capped teeth, autosomal dominant?
Type lllA Autosomal dominant
Type lllB Autosomal recessive
Type lV Hypomaturation-hypoplastic with taurodontism
Type lVA Hypomaturation-hypoplastic with taurodontism, autosomal dominant
Type lVB Hypomaturation-hypoplastic with taurodontism, autosomal recessive

Hart et al, 2002 Proposed a molecular defect sub classification of the AMELX condition

1.1 Genomic DNA sequence

1.2 cDNA sequence

1.3 Amino acid sequence

1.4 Nucleotide and amino-acid sequence

1.5 AMELX mutations described to date

Aldred et al, 2003

Classification based on:

Mode of inheritance

Phenotype- Clinical and Radiographic

Molecular defect (when known)

Biochemical result (when known)

X-Linked forms of Amelogenesis Imperfecta

This is also known as Amelogenesis Imperfecta 1or hypo plastic type. It is observed that heterozygous females pass on the mutant gene to children of both sexes with the risk of 50%. However, the affected males and females express the condition differently. Males exhibit only a thin layer of enamel of normal color and translucency; it can also be normal thickness enamel but have poor mineralization which gives rise to loss of translucency and a yellow-brown discoloration. Some families also exhibit a combination of Hypoplasia and abnormal mineralization occurring together. The affected individual may also exhibit sensitivity to thermal and osmotic stimuli along with the predominant phenotype of Hypoplasia. In case of affected females, they show vertical markings on the enamel due to X chromosome inactivation, which is also known as Lysonisation. Therefore they are observed to have teeth with vertical ridges or grooves due to Hypoplasia or also exhibit vertical bands of alternating normal and discolored enamel [30].

Genetic mapping have suggested that the X-linked disease to Xp22 region of the short arm of the X chromosome and these subsequently result in mutation of AMELX gene [30].

Amelogenin gene (OMOM*300391)

This gene codes for the amelogenin protein. It has seven exons that span over nine kilo bases. The mutations reported on this gene include deletions on some parts of the gene, single base mutations and premature stop codons as well. They play a critical role in controlling the enamel thickness and enamel mineralization. The studies conducted show no evidences of pre-mutations in this gene. Also there are no evidences of mutation in the amelogenin gene AMELY (Yp11) on the Y chromosome or their role in enamel formation. But it has been suggested that the Y site contributed to the tooth size [30].

Autosomal forms of Amelogenesis Imperfecta

The positional cloning done in some families suggest that the autosomal dominant Amelogenesis Imperfecta maps in 4q11-q21. The genes involved include albumin ALB, ameloblastin AMBN and enamelin ENAM. These genes map the same region and are considered as candidate genes for autosomal dominant Amelogenesis Imperfecta. Another protein named Tuftelin, which maps the 1 q21, has also been named as a cause for other cases of autosomal Amelogenesis Imperfecta. Studies have also shown that genes that code for enamel proteases, which are necessary to degrade enamel proteins, will also cause Amelogenesis Imperfecta [27].

Autosomal Dominant Amelogenesis Imperfecta

This form of the disease is observed to affect one or more individuals in each generation of the family. The clinical signs may be consistent for each affected member or may vary from person to person, even if the affected individuals may belong to the same family.

This type of Amelogenesis Imperfecta is predominantly hypo plastic in some families and can be characterized by thin enamel and spacing between teeth. Other individuals may also present with rough, irregular or randomly pitted enamel. The affected may present with hard enamel, which are normally translucent and not affected by significant attrition if the primary defect is in the production of adequate amount of enamel matrix. It is also observed that some families have an exclusive or predominant hypomineralised phenotype of the disease. For ease of classification, these defects have been named as demineralization to explain the spectrum of defects of mineralization in Amelogenesis Imperfecta. The most severe form of

demineralization is observed to have “cheesy” enamel that is easily lost which leads to reduction in tooth size and increased sensitivity [27].

Some cases show a combination of both enamel Hypoplasia and demineralization which is expressed as teeth with reduced size ab initio that have lesser enamel, small crowns with spacing and can also exhibit yellowish hue due to mineralization defect [27].

ENAM 4q21

The enamelin gene (ENAM) is mapped to chromosome 4q to the same region that is mapped for Amelogenesis Imperfecta 2. A study has reported an extensive family where the causative gene was mapped to 4q11-q21. Another study performed in Japan suggested that the extended family had a similar phenotype wherein the condition was linked to a single G-deletion. Another study performed by Mardh et al, traced a local, hypo plastic form of the autosomal dominant inherited Amelogenesis Imperfecta that was caused due to a nonsense mutation in the enamelin gene. This resulted in the localized Hypoplasia in contrast to a generalized form that occurs due to a “splice-site” mutation [34]. Another study by Kim et al, helps to relate phenotype to genotype and helps in identification of a mid-crown, horizontal form of Hypoplasia [35].

Chromosome 8q24.3

This chromosome has been found as an additional locus for autosomal dominant Amelogenesis Imperfecta [36].

Autosomal Recessive Amelogenesis Imperfecta

This form of the disease is most often encountered in ethnic or family groups where intermarriage between relatives is more common such as Amelogenesis Imperfecta that is caused due to cone rod dystrophy, which is a syndromic condition. Autosomal recessive Amelogenesis Imperfecta is also prevalent in cases there is a high frequency of mutant gene in the population as seen in some of the Polynesian communities [27].

ENAM 4q21

These genes exhibit Amelogenesis Imperfecta, which is hypo plastic in type and is also observed to show open bite malocclusion with hypo plastic enamel, which can be seen as localized enamel pitting in certain cases. Studies suggested that in

homozygous individuals the ENAM mutation in chromosome 4 showed enamel pitting and an anterior open bite while the heterozygous individuals presented with only enamel pitting. This variation has been attributed to “dose dependency” wherein generalized hypo plastic Amelogenesis Imperfecta is a recessive trait and localized enamel pitting is seen as a dominant trait [29].

Other studies done in the same center evaluated nine Jordanian families affected with autosomal recessive Amelogenesis Imperfecta on the basis of clinical, familial, radiographic, and microscopic and protein levels. This resulted in finding a wide spectrum of phenotypes, which supported the earlier inheritance pattern suggested but also stated four different sub-types of autosomal recessive Amelogenesis Imperfecta [37]. The gene KLK4 that maps chromosome 19q13.4 has been associated with the formation of autosomal recessive hypo maturation Amelogenesis Imperfecta [29].

MMP-20

The mutation in the region of 11q22.3-q23 of the matrix metalloproteinase 20 gene has been identified to cause autosomal recessive pigmented hypo maturation Amelogenesis Imperfecta [29].

Sporadic Cases of AmelogenesisImperfecta

The sporadic cases of Amelogenesis Imperfecta can be caused due to a number of reasons. They can be representatives of autosomal recessive Amelogenesis Imperfecta, may be caused due to a new mutation or they may be an example of variable expression with or without incomplete penetrance of a dominant gene. This aspect emphasizes on the fact that proper clinical examination of other family members is important to avoid wrongly classified Amelogenesis Imperfecta case. Also, the tooth abnormality may be caused by non-genetic reasons such as fluorosis and tetracycline staining. When studying other genetic disorders we can observe the passage of new mutations as a autosomal dominant trait but this has not been conclusively proven in the case of Amelogenesis Imperfecta.

In the recent years, a condition known as Molar-Incisor Hypomineralisation (MIH) has been identified. The etiological condition of this disease is unknown but is observed to affect one or more first permanent molars and the anterior teeth in an

unrelated pattern. However, this condition is not yet classified under Amelogenesis Imperfecta yet.

Association of AmelogenesisImperfecta with Syndromes

Earlier the strict definition of Amelogenesis Imperfecta suggested it is an enamel defect that does not include other structures. But such narrow restrictions cannot be applied to a condition that varies in development and progression among different families. Therefore, it has been suggested that Amelogenesis Imperfecta is a genetic condition that may occur in combination with other syndromes or as a separate entity. It has also been explained that the condition may occur due to a single gene defect or from a microsomal or chromosomal defect. The association of Amelogenesis Imperfecta with cone-rod dystrophy is an example [27].

AmelogenesisImperfecta as a Syndrome

In about 50% of the cased affected with this condition, either an X-linked or autosomal inheritance, an anterior open bite is present. This association may be considered as a syndrome but no such mention has been made in any classification yet, it is still a topic to be elucidated.

The phenotypic classifications of Amelogenesis Imperfecta have included taurodontism as an intrinsic feature in one of the variants- AI with taurodontism (AIT). This classification is reasonable as taurodontism is an ectodermal trait. The Hertwig's epithelial root sheath (HERS), which maps the shape of the tooth and root is derived from the enamel organ and helps I n the differentiation of inner enamel epithelium cells into ameloblasts that later form the enamel.

AmelogenesisImperfecta in Syndromes

Recently there have been similarities found between AIT and the tricho-dento-osseous (TDO) defect that includes additional features such as bony defects like bone sclerosis and hair feature of "curly hair". The hair changes and the enamel defect are explained as ectodermal changes but the bony defects occur by a different pathway, which is primarily of mesoderm origin. It is observed that TDO occurs due to a mutation in DLX3 gene. One study reported that Amelogenesis Imperfecta and TDO are genetically distinct, while another study that was conducted later suggests that

TDO and Amelogenesis Imperfecta hypoplastic-hypomaturation with taurodontism (AIHHT) are allelic for DLX3 [27].

There ismany other AI like changes which are associated with other whole body findings but are not included in the diagnosis of Amelogenesis Imperfecta. If it is to be accepted that Amelogenesis Imperfecta can occur as a insolated trait as well as in association with other syndromes, ten many conditions have to be considered in the differential diagnosis of enamel defects. Some syndromes to present with enamel defects include Kohlschutter syndrome, Platypondyly with Amelogenesis Imperfecta, Amelogenesis Imperfecta and nephrocalcinosis, cone-rod dystrophy and Amelogenesis Imperfecta.

The correlation between hypo plastic Amelogenesis Imperfecta and nephrocalcinosis emphasizes on renal examination in patients diagnosed with Amelogenesis Imperfecta [38].

Enamel Defects other than AmelogenesisImperfecta in Syndromes

The meticulous differential diagnosis of causes of the enamel defect in a patient is necessary for therapeutic, professional and patient personal reasons. Many alternative causes can be attributed to an enamel defect. For example, regional odontoplasia is not a primary differential diagnosis in a case of a localized defect of central incisor, which is coupled with the non-eruption of an adjacent tooth. This case can be mainly diagnosed to have occurred due to a childhood trauma that had affected the eruption of the unerupted tooth. Many families are affected by such conditions and thus it is necessary for careful diagnosis, mainly in relation to inheritance of such defects [27].

Clinical Description

Amelogenesis imperfect affects the enamel of all teeth irrespective of inheritance pattern and chronology of the teeth and at occasions, it can be associated with syndromes as well. When an individual is affected with this condition, the enamel can be hypo plastic, hypomineralised or a combination of both. The affected teeth are observed to be discolored, sensitive and prone to disintegration either in pre-eruptive period or in the post – eruptive period [27]. It either occurs due to a single defect or due to micro deletion and chromosomal defect as seen in the case of Cone-red

dystrophy associated with Amelogenesis imperfect, that shows linkage of 2q11[39][40].

Diagnostic Methods

Clinically obtaining a family history, clinical observation, preparing a pedigree plotting is essential to diagnose the condition like any other inherited disease. Radiographic examination of these individuals may help us detect unerupted and resorbing teeth present. In combination with the clinical observation, these records help us identify the extent of enamel Hypoplasia that has occurred in the patient. However, laboratory genetic diagnosis is still under research [27].

Differential Diagnosis

The extrinsic disorders of tooth formation, chronological disorders of tooth formation and localized disorders of tooth formation are primary conditions to be considered during differential diagnosis.

The most common differential diagnosis includes dental fluorosis. This condition may vary from mild white flecking of the enamel to dense areas of discoloration with randomized staining and Hypoplasia. Fluorosis may present with horizontal banding that occurs due to intense fluoride intake that may have spared the premolars and second permanent molars to be spread, a chronological distribution is observed. The latter case can be mainly due to reasons such as local water supply or habits like eating toothpaste in childhood.

Similar findings can also be observed can be due to various causes at the time of tooth formation such as gastrointestinal upset of a prolonged nature as seen in celiac disease and anti- leukemic therapy. These conditions can be found from the history and the chronological distributions of the markings seen. [27]

Treatment

The treatment planning for individuals affected is more radical and stats at a very early age. It is observed that the disease has a profound effect on the emotional status of the patient as many cases have been reported where the patient becomes withdrawn, reclusive and even threatens suicide due to their deformed teeth [41]. Patients are known to have covered their teeth with pieces of paper, chewing gum or other materials to mimic a normal appearance of their teeth. Many people affected

with Amelogenesis Imperfecta have been observed to request to remove their teeth and the fitting of dentures in a society where one's own teeth are the preferred option. The treatment process is described to go through a temporary phase to reach a transitory phase. The primary dentition is protected by the use of metal crowns in the posterior teeth and, composite restorations and polycarbonate crowns are used in the anterior teeth [42]. In case of permanent dentition, if the patient has less hypomineralised and more hypo plastic teeth then usage of preformed crows to maintain the oral hygiene is a viable option. The malocclusion that is also observed to occur in these patients must be corrected by the combined efforts of the clinician and an orthodontist [43].

Conclusion

Due to advancement in pre and postnatal care of premature children, the reported cases of developmental enamel defects are on the rise. Therefore it is necessary that the clinician is well informed about the initiation and progression of the condition to systematically treat the same.

Abstract

Cardiovascular diseases are a group of disorders that involve the heart and/or blood vessels. CVD are a spectrum of diseases that includes coronary heart disease, hypertensive heart disease, rheumatic heart disease, cardiomyopathy and cardiac arrhythmias etc. Cardiovascular involvement in diabetes is a common occurrence and in fact, CVD is the leading cause of early death among people with diabetes—about 65 percent of people with diabetes die from heart disease and stroke. High blood glucose levels damage nerves and blood vessels, leading to complications such as heart disease and stroke, the leading causes of death among people with diabetes. Uncontrolled diabetes can eventually lead to other health problems as well, such as vision loss, kidney failure, and amputations.

Key Words: *Glucose levels, Stroke, Health, Kidney, Uncontrolled diabetes*

Introduction

Cardiovascular disease is a class of diseases that occur in heart or blood vessels. CVD includes angina, myocardial infarction, hypertensive heart disease, rheumatic heart disease, cardiomyopathy, atrial fibrillation, endocarditis and venous thrombosis. CVD is a major complication of diabetes and the leading cause of early death among people with diabetes—about 65 percent of people with diabetes die from heart disease and stroke [1]. High blood glucose levels damage nerves and blood vessels, leading to complications such as heart disease and stroke, the leading causes of death among people with diabetes. Uncontrolled diabetes can eventually lead to other health problems as well, such as vision loss, kidney failure, and limb amputations. Cardiovascular diseases (CVD), comprising coronary heart (CHD) and cerebrovascular diseases, are currently the leading cause of death globally, accounting for 21.9 per cent of total deaths, and are projected to increase to 26.3 per cent by 2030 [2]. The number of people with diabetes mellitus is alarmingly increasing due to the growing prevalence of obesity, genetic susceptibility, urbanization, and aging [3].

Diabetes mellitus is a chronic disease which has been described as a state of raised blood glucose associated with premature mortality. Diabetes is an important chronic disease which incidence is globally increasing and though considered as an epidemic [4]. It arises when the pancreas fails to produce enough insulin (type 1 diabetes), or when the body cannot effectively make use of the insulin produced (type 2 diabetes). Failure of insulin secretion, action or both leads to raised blood glucose and other metabolic changes which, if uncontrolled, can cause serious complications [5]. The most important of these are retinopathy (affecting the eyes), nephropathy (affecting the kidneys), neuropathy (affecting the nerves) and cardiovascular disease (affecting the circulatory system) [6]. Diabetes is fast becoming a world pandemic. Although there is no evidence that type 1 diabetes is preventable, it is clear that modifiable factors exist for type 2 diabetes. If action is not taken to stem the tide of type 2 diabetes, the prospects for world health are bleak [7].

Diabetes

Diabetes mellitus is a chronic disease which has been described as a state of raised blood glucose associated with premature mortality. Itarises when the pancreas fails to produce

enough insulin (type 1 diabetes), or when the body cannot effectively make use of the insulin produced (type 2 diabetes). Failure of insulin secretion, action or both leads to raised blood glucose and other metabolic changes which, if uncontrolled, can cause serious complications [5]. The most important of these are retinopathy (affecting the eyes), nephropathy (affecting the kidneys), neuropathy (affecting the nerves) and cardiovascular disease (affecting the circulatory system) [6].Diabetes is fast becoming a world pandemic. Although there is no evidence that type 1 diabetes is preventable, it is clear that modifiable factors exist for type 2 diabetes. If action is not taken to stem the tide of type 2 diabetes, the prospects for world health are bleak [7]. A regular energy source is a prerequisite for every cell to function in the human body. Glucose is the body's primary energy source, which circulates in the blood as a mobilizable fuel source for cells [8,9,10]. Insulin is a pancreatic hormone responsible for blood glucoseregulation. The hormone binds to its receptor sites on peripheral side of the cell membranes. It affords entry of glucose into respiring cells and tissues via requisite channels. Insulin stimulates catabolism on glucose into pyruvate through glycolysis. It also upregulates glycogenesis from excessive cytosolic glucose and lipogenesis from excessive cytosolic acetyl-COA. These metabolic events are antagonistic to metabolic events triggered by the hormone glucagon. When glucose levels are at or below threshold, glucose stays in the blood instead of entering the cells [11]. The prevalence of diabetes increases with age in all race/ethnicity groups [12].

The body attempts to arrest hyperglycemia, by drawing water out of the cells and into the bloodstream. The excess sugar is excreted in the urine. This is why diabetics present with constant thirst, drinking large amounts of water, and polyuria as the cells try to get rid of the extra glucose. This subsequently leads to glucosuria[8].

Classification

One problem over the years has been the classification of diabetes into different categories. Most recently, a World Health Organization (WHO) Consultation and the American Diabetes Association (ADA) Expert Committee have divided diabetes into four main types. What was

previously known as insulin dependent diabetes mellitus (IDDM) has become type 1 diabetes under this now,

Table 1: Types of Diabetes

Type 1 diabetes	Insulin required for survival- due to a lack of insulinproduced by the body as a result of beta cell destruction.
Type 2 diabetes	• Characterized by disorders of both insulin action or secretion, either of which may predominate, but both of which are usually present. Usually controlled by diet, exercise and oral hypoglycemic agents. Insulin may be required for metabolic control.
Other specific types of diabetes	Other types of diabetes where the cause is known (eg: genetic defects in beta cell function or insulin action, diseases of the pancreas, certain other hormonal disorders,or drug induced disorders).

Risk Factors of Type 2 Diabetes

- Ethnicity
- Family history
- Obesity (particularly central)
- Physical inactivity
- Urbanization and mechanization
- Westernized diet
- Age

Cardiovascular Diseases

Globally, myocardial infarction is an important cause of premature death. Among its well-established modifiable risk factors are hypertension, dyslipidemia, smoking, and diabetes.[13]. Cardiovascular diseases are diseases that affect the heart and circulatory system. In developing

countries,the most common cause ofcardiovascular disease used to be infection ofthe heart valves. However, in recent years therehas been a shift away from infectious causes inmany developing nations. Today the mostwidespread form of cardiovascular diseasearound the world is that which starts with damage to the blood vessels[14]. Atherosclerosis is an immuno-in ammatory disease which occurs mainly in the large and medium sized arteries [15].

The two main processes by which the blood vessels become damaged are atherosclerosis and hypertension:

1. Atherosclerosis leads to the formation of plaques of atheroma which narrow the diameter of the large and medium-sized arteries. This narrowing of the arteries impairs blood flow. Plaques are also prone to rupture or to ulcerate and then act as a site for blood clot formation. The resulting blood clots, which can block the affected vessel completely, are usually responsible for the more severe clinical manifestations of cardiovascular disease such as heartattack and stroke.

2. Hypertension damages the smaller vessels in the circulatory system. Over time they become scarred, hardened, narrowed and less elastic. Hypertension can also both predispose to and accelerate the development of atherosclerosis [16].

Clinical Manifestation

The major clinical manifestations of cardiovascular disease can be divided into three groups:

1. Those affecting heart and coronary circulation (coronary heart disease).
2. those affecting the brain and cerebral circulation (cerebro-vascular disease); and
3. those affecting the lower limbs (peripheral vascular disease).[16,17]

Risk Factors of Cardiovascular Diseases

- Advancing age
- Diabetes and other high blood glucose conditions
- Dyslipidemia
- Genetic background
- High alcohol consumption
- Hypertension

- Insulin resistance
- Male gender
- Menopause
- Obesity
- Sedentary lifestyle
- Smoking

Pathophysiology

The pathophysiology of the link between diabetes and cardiovascular disease (CVD) is complex and multifactorial. Understanding these profound mechanisms of disease can help clinicians identify and treat CVD in patients with diabetes, as well as help patients prevent these potentially devastating complications. The endothelium, the innermost layer of blood vessels, is an active organ that regulates multiple vascular functions. It not only acts as a barrier but also regulates vascular growth, platelet function, and coagulation. When the endothelium is healthy, it releases nitric oxide (NO) and maintains a balance between various functions such as dilatation/constriction, growth inhibition/promotion, antithrombosis/prothrombosis, and anti-inflammation/proinflammation[18]. This article reviews the biological basis of the link between diabetes and CVD, from defects in the vasculature to the cellular and molecular mechanisms specific to insulin-resistant states and hyperglycemia. Insulin resistance and several other factors related to central adiposity have been implicated in endothelial dysfunction. Hyperglycemia induces free radical production and increases superoxide production and oxidative stress, which contributes to atherogenesis. Hyperglycemia also augments the expression of adipokines, further inducing adipokine-related endothelial dysfunction. Additionally, impaired insulin action in adipose tissue results in elevated rates of lipolysis and free fatty acid (FFA) release [19].

Macrovascular

Atherosclerosis is the major threat to the macrovasculature for patients with and without diabetes. Clinically, dyslipidemia is highly correlated with atherosclerosis, and up to 97% of patients with diabetes are dyslipidemic[20]. In addition to the characteristic pattern of increased triglycerides and decreased HDL cholesterol found in the plasma of patients with diabetes, abnormalities are seen in the structure of the lipoprotein particles. In diabetes, the predominant

form of LDL cholesterol is the small, dense form. Small LDL particles are more atherogenic than large LDL particles because they can more easily penetrate and form stronger attachments to the arterial wall, and they are more susceptible to oxidation. Because less cholesterol is carried in the core of small LDL particles than in the core of large particles, subjects with predominantly small LDL particles have higher numbers of particles at comparable LDL cholesterol levels [21].

Moreover, diabetic blood is more likely to be high in triglycerides. Dyslipidemia is only one mechanism by which diabetes promotes atherosclerosis; endothelial dysfunction often contributes. Healthy endothelium regulates blood vessel tone, platelet activation, leukocyte adhesion, thrombogenesis, and inflammation. The net effect of healthy endothelium is vasodilatory, anti-atherogenic, and anti-inflammatory [22].

When these mechanisms are defective, the process of atherosclerosis is accelerated. Therefore, both insulin deficiency and insulin resistance promote dyslipidemia accompanied by increased oxidation, glycosylation, and triglyceride enrichment of lipoproteins. In addition, endothelial dysfunction is present, and all of these factors contribute to the increase in atherogenicity, and thus macrovascular disease, found in patients with diabetes[23].

- Macrovascular
    1. Peripheral vascular disease
    2. Ischaemic heart disease
    3. Stroke
- Microvascular
    1. Nephropathy
    2. Neuropathy
    3. Retinopathy

Microvascular

Microvascular disease" associated with diabetes, we think of retinopathy, nephropathy, and neuropathy. In addition, however, small vessels throughout the body are affected by diabetes,

including those in the brain, heart, and peripheral vasculature. This small vessel damage is typically not related to atherosclerosis and is not predicted by lipid levels. [24].

Table 2: Prevalence of cardiovascular risk factors in people with diabetes compared to people without diabetes.

Hypertension	Prevalence is at least double in people with type 2 diabetes
High blood cholesterol	Prevalence is similar in people with diabetes.
High triglycerides with low HDL	Prevalence is higher in people with diabetes
Left ventricular hypertrophy	Most commonly seen in people with long-standing high blood pressure, but is also seen in the absence of elevated blood pressure in people with diabetes
Obesity	Prevalence is stronger in people with diabetes. Weight distribution is also usually different, with more central obesity which is linked with a tendency to develop coronary heart disease
Smoking	People with diabetes smoke less (presumably due to medical advice)

Table 3: Targets for common cardiovascular risk factors in people with diabetes

RISK FACTORS	**TARGETS**
Dyslipidaemia	• Decrease LDL cholesterollevels (<115mg/dl or 3 mmol/l*) • Raise HDL cholesterol levels (>46 mg/dl or 1.2 mmol/l*) • Lower triglycerides (<150 mg/dl or 1.7 mmol/l*)

Hypertension	• Lower blood pressure (<135/85 mm Hg).
Hyperglycaemia	• Reduce hyperglycaemia(HbA1c <7%)

Diabetes and its Relation to Cardiovascular Diseases

Diabetics have an increased risk of cardiovascular morbidity and mortality[25]. They particularly have an increased risk of congestive failure[26]. Diabetics in less affluent societies have fewer cardiovascular complications compared with non-diabetics in the same area and to diabetics inaffluent societies [27].

This suggeststhatnotall diabetesisthesame orthatother factorsmarkedlyinfluence itsimpacton health.Diabetesmellituswasoriginallyconsidered a simple consequence of a pancreasunable to produceenoughinsulin,causingtheblood sugar tobecomeunduly elevatedwhich,inturn, produced a series of disastrous metabolicalterationsculminatingincoma anddeath. Current concepts are more complex.Diabetesbeginning in childhood is usually due to severe insulin deficiency; when it firstappears inadultlife,itisoften associatedwithnormalor increasedinsulin levels.In the latter case, something interfering with insulin utilizationseems more likely. Theelevatedbloodpressure ofdiabetics had reported previously [28]. Incomparisonsoflipidvalues ofdiabetics andnon-diabetics,diabeticshavegenerallybeenfoundtohave elevated cholesterolvalues[29,30,31]. Other studies have indicated that diabetics who develop atheroscleroticcomplications have higher cholesterol values than thosewhodonot, [32] buttheredoesnot appear to have been any previous analysisofpossibleinteraction between cholesterol and diabetes.

Treatment

People with stable angina are usually treated by tight control of cardiovascular risk factorsand by prescribing drugs (eg: aspirin, beta blockers, nitrates and long-acting calcium channel blockers) [33]. When unstable angina develops, the risk of heart attack is very high and rapid preventive treatment in an intensive or coronary care unit may be required. People with diabetes who have experienced an acute heart attack benefit to the same degree, and in some cases even more, from therapeutic interventions that are used in people without diabetes [34].

Table 4: Effectiveness of medication in people with Diabetes

TREATMENT	EFFECTIVENESS IN PEOPLE WITH DIABETES
Aspirin •	Equally effective
Beta-blockers	• Equally effective
ACE inhibitors	• Particularly advantageous if started within 24 hours
Statins	• Equally effective
Clot dissolving	Useful within the first few hours only

Conclusion

Atherosclerosis is a major contributor to the morbidity and mortality observed in DM. The development of atherosclerosis is not only a result of hyperglycemia, but also from the secondary insulin resistance, dyslipidemia, hypercoagulability, altered secretion and function of local regulatory substances, and impaired response to injury. Strict glucose control alone is insufficient and a multifaceted approach targeting all mechanisms is required.

Diabetic Peripheral Neuropathy – A Review

Karthic.A [1], Remmiya Mary Varghese [2]

Graduate Student [1], Senior Lecturer [2], Department of Orthodontics

Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences,

Saveetha University, Chennai, India

Abstract

Peripheral neuropathy is a micro vascular complication of diabetes and is a frequent cause of morbidity and disability. The various risk factors associated with Diabetic peripheral neuropathy (DPN) includes smoking, heavy alcohol use, dyslipidemia, duration of diabetes and genetic profile. DPN is usually symmetrical and affects distal extremities and hence it is also referred as distal symmetric polyneuropathy. Patients with DPN may be asymptomatic or present with symptoms such as paraesthesia, numbness, tingling sensation and loss of ankle jerk. Nerve conduction study will detect DPN even if patient is asymptomatic.

Key Words*: Diabetic peripheral neuropathy, morbidity, disability.*

Introduction

Diabetic peripheral neuropathy (DPN), likewise alluded to as distal symmetric polyneuropathy (DSP), is the nearness of side effects and additionally indications of fringe nerve brokenness in patients with diabetes after different reasons for brokenness have been excluded.[1]Diabetes mellitus is a critical reason for fringe neuropathy, representing half of all cases. The frequency of DPN is high in patients with diabetes, Another investigation, which characterized neuropathy as reciprocal nonappearance of lower leg jerks as well as vibratory misfortune, detailed a predominance of 70% in patients who have had type 2 diabetes for a long time or progressively [2,3] Recent examinations have evaluated that the pervasiveness of difficult DPN among diabetic patients is 20%.[4]Many of these patients and additionally the greater part of those with easy DPN are uninformed of their neuropathy. Easy neuropathy can be especially hazardous in light of the fact that patients will most likely be unable to distinguish damage to the foot (eg, get scorched from a hot shower, venture on a sharp question, or build up a rankle from a tight shoe). If not perceived and treated forcefully and rapidly, these wounds may bring about foot ulcers, contamination and even amputation.

Diabetes has turned out to be one of the biggest worldwide social insurance issues of the 21 st century. The quantity of individuals with diabetes worldwide is anticipated to twofold in the vicinity of 2000 and 2030, achieving a pandemic level of 366 million individuals. Diabetic polyneuropathy (DPN), which has a lifetime predominance of around half, is the most well-known diabetic difficulty. DPN is a main source for handicap because of foot ulceration and removal, walk unsettling influence, and fall-related damage. Roughly 20 to 30% of patients with DPN experience the ill effects of neuropathic torment. DPN fundamentally brings down personal satisfaction and considerably expands wellbeing costs related with diabetes.

Excruciating diabetic neuropathy (PDN) side effects display a symmetrical "stocking and gloves" appropriation and are o en related with nighttime compounding. It can be displayed from a mellow sticks and needle sensation to wounding, consuming, unremitting, or even upsetting electric stun sensation. Ere can be allodynia as cutaneous hypersensitivity prompting intense trouble on contact with an outer jolt, for example, apparel. The torment is regularly more terrible during the evening and frequently irritates rest, causing tiredness amid the day. A few patients give upsetting allodynia and serious agony in the legs. Is might be painful to the point that it

keeps them from playing out their day by day exercises, subsequently affecting their work and social life. E steady, unremitting torment and withdrawal from social life often result in discouragement. In outrageous cases, patients lose their craving and experience significant weight reduction, which which is reported in the literature as “diabetic neuropathic cachexia”

Physiology of Pain

Pain is the body's impression of real or potential harm to the nerve or tissue by poisonous boosts. tangible an afferent nerves convey sensations from the skin, joints, and viscera by means of huge and little fibres. Expansivefibres, for example, an alpha, are in charge of appendage proprioception and A-beta fibres convey vibes of appendage proprioception, weight, and vibration. Vast A-delta myelinatedfibresand little C unmyelinatedfibresare mostly in charge of conveying nociceptive sensations. Superficial torment is o en a sharp or pricking sensation and is transmitted by A-delta fibres. A profound situated, consuming, tingling, hurting sort of torment is o en went with hyperalgesia and allodynia and is transmitted by means of moderate, unmyelinated C fibres. Tissue harm brings about the arrival of inflammatory chemicals, for example, prostaglandins, bradykinins, and histamines, at the site of inflammation, which triggers the depolarization of nociceptors, along these lines producing an activity potential. e activity potential transmits the nociceptive sensation, by means of the dorsal root ganglion (DRG), to the dorsal horn of the spinal line. e arrival of glutamate and substance P brings about the hand-off of nociceptive sensations to the spinothalamic tract, thalamus, and, hence, the cortex, where torment is translated and seen.

Nociceptive agony is the typical reaction to toxic affront or damage of tissues, for example, skin, muscles, instinctive organs, and joints. Nociceptive torment more often than not dies down upon the mending of the tissue damage. Then again, neuropathic torment emerges as an immediate result of an injury or illness an etching the somatosensory framework with no poisonous jolts. Neuropathic torment is caused by harm or neurotic change and is portrayed by the actuation of anomalous pathways of agony at the fringe nerves and back roots (fringe neuropathic torment) or spinal string and mind (focal torment). Neuropathic torment appearance can be central,

multifocal, or summed up contingent upon the association of fringe or focal root and reason for the sickness.

Pathophysiology

Neuropathic Pain is a perplexing, ceaseless pain express that more often than not is joined by tissue damage. Usually in clinical practice and exhibits a test to patients and clinicians alike. With neuropathic torment, the nerve strands are harmed may end up useless or harmed. Neuropathic Agony is the aftereffect of ailment or damage to the fringe or focal sensory system (spinal or supra spinal sensory system) and the injury may happen anytime. These harmed nerve strands incorporate an adjustment in nerve work both at the site of the damage and territories around the damage and they send off base signs to other agony focuses. The effect of a nerve fiber damage incorporates an adjustment in nerve work—both at the site of the damage and zones around the damage. Clinical signs of Neuropathic Agony normally incorporate positive tangible marvels, for example, unconstrained torment, paraesthesia, allodynia, and hyperalgesia. Highlights that separate Neuropathic Agony from different kinds of torment incorporate torment and tactile manifestations enduring past the recuperating time frame.

The speculations with respect to the pathophysiology of Neuropathic Agony are numerous. Before going into subtle elements, a short audit with respect to torment circuit is required. There are two kinds of agony circuits: facilitatory and inhibitory circuits' facilitatory circuit in charge of torment sensation, and is especially interceded by glutamate (excitatory neurotransmitter) intervened receptors. The inhibitory circuits cause torment concealment for the most part intervened by GABA (gamma amino butyric corrosive), which is an inhibitory neurotransmitter. The system basic neuropathic torment, notwithstanding, isn't as clear. A few creature considers have demonstrated that numerous components might be included. To begin with arrange neurons may expand their terminating on the off chance that they are somewhat harmed because of increment in the quantity of sodium channels and therefore upgraded depolarization prompts unconstrained torment and development related agony. Impedance of Inhibitory circuits at the level of the dorsal horn or cerebrum stem permits uninhibited transmission of torment driving forces. Likewise, there are a few changes in the focal preparing of agony where there is

expanded the affectability of spinal neurons and abatement in actuation edges bringing about focal refinement marvel working in patients of diabetic neuropathy. Raja, et al. in an intriguing examination portrayed that barricade of α - adrenergic receptor work with intravenous imbuement of the rival phentolamine additionally prompts relief from discomfort. In this way, there likewise can be the connection of the thoughtful sensory system towards neuropathic torment.

The correct instrument of nerve harm in diabetic neuropathy is as yet misty, metabolic and vascular/hypoxic factors seem, by all accounts, to be included. Propel Glycosylation Finished results (AGEP) may harm vessels; repress axonal transport prompting axonal degeneration. Increment generation of sorbitol because of actuation of polyol pathway causes basic nerve harm. Additionally, expanded endoneurial vascular protection from hyperglycemic blood can prompt nerve ischemia.

Etiology

Diabetic neuropathy is a type of nerve damage that can occur who have diabetes. High blood sugar can injure nerve fibers throughout your body, but diabetic neuropathy most often damages nerves in legs and feet.[5] Depending on the affected nerves, symptoms of diabetic neuropathy can range from pain and numbness in extremities to problems with digestive system, urinary tract, blood vessels and heart. For some people, these symptoms are mild; for others, diabetic neuropathy can be painful, disabling and even fatal. Diabetic neuropathy is a common serious complication of diabetes. Prolonged exposure to high blood sugar can damage delicate nerve fibers, causing diabetic neuropathy. [6]Why this happens isn't completely clear, but a combination of factors likely plays a role, including the complex interaction between nerves and blood vessels. High blood sugar interferes with the ability of the nerves to transmit signals. It also weakens the walls of the small blood vessels (capillaries) that supply the nerves with oxygen and nutrients.[7] Other factors that may contribute to diabetic neuropathy include:

- **Inflammation in the nerves** caused by an autoimmune response. This occurs when immune system mistakenly attacks part of body as if it were a foreign organism.

- **Genetic factors** unrelated to diabetes that make some people more susceptible to nerve damage.
- **Smoking and alcohol abuse,** which damage both nerves and blood vessels and significantly increase the risk of infections.

Symptoms

There are four main types of diabetic neuropathy. The signs and symptoms of diabetic neuropathy vary, depending on the type of neuropathy and which nerves are affected.

Peripheral neuropathy

Peripheral neuropathy is the most common form of diabetic neuropathy. Feet and legs are often affected first, followed by hands and arms. [8]Signs and symptoms of peripheral neuropathy are often worse at night, and may include:

- Numbness or reduced ability to feel pain or temperature changes
- A tingling or burning sensation
- Sharp pains or cramps
- Increased sensitivity to touch
- Muscle weakness
- Loss of reflexes, especially in the ankle
- Loss of balance and coordination
- Serious foot problems, such as ulcers, infections, deformities, and bone and joint pain

Autonomic neuropathy The autonomic nervous system controls heart, bladder, lungs, stomach, intestines, sex organs and eyes. [9, 8]Diabetes can affect the nerves in any of these areas, possibly causing:

- A lack of awareness that blood sugar levels are low (hypoglycemia unawareness)
- Bladder problems, including urinary tract infections or urinary retention or incontinence
- Constipation, uncontrolled diarrhea or a combination of the two
- Slow stomach emptying (gastroparesis), leading to nausea, vomiting, bloating and loss of appetite
- Difficulty swallowing
- Erectile dysfunction in men
- Increased or decreased sweating
- Inability of body to adjust blood pressure and heart rate, leading to sharp drops in blood pressure after sitting or standing that may cause you to faint or feel lightheaded
- Problems regulating your body temperature
- Changes in the way your eyes adjust from light to dark

RadiculoplexusNeuropathy (Diabetic Amyotrophy)

Radiculoplexus neuropathy affects nerves in the thighs, hips, buttocks or legs. Also called diabetic amyotrophy, femoral neuropathy or proximal neuropathy, this condition is more common in people with type 2 diabetes and older adults. Symptoms are usually on one side of the body, though in some cases symptoms may spread to the other side. Most people improve at least partially over time, though symptoms may worsen before they get better. This condition is often marked by:

- Sudden, severe pain in your hip and thigh or buttock
- Eventual weak and atrophied thigh muscles

- Difficulty rising from a sitting position
- Abdominal swelling, if the abdomen is affected
- Weight loss

Mononeuropathy

Mononeuropathy involves damage to a specific nerve. The nerve may be in the face, torso or leg. Mononeuropathy, also called focal neuropathy, often comes on suddenly [11, 12] It's most common in older adults. Although mononeuropathy can cause severe pain, it usually doesn't cause any long term problems. Symptoms usually diminish and disappear on their own over a few weeks or months. Signs and symptoms depend on which nerve is involved and may include:

- Difficulty focusing your eyes, double vision or aching behind one eye
- Paralysis on one side of your face (Bell's palsy)
- Pain in shin or foot
- Pain in lower back or pelvis
- Pain in the front of your thigh
- Pain in chest or abdomen

Sometimes mononeuropathy occurs when a nerve is compressed. Carpal tunnel syndrome is a common type of compression neuropathy in people with diabetes.

Signs and symptoms of carpal tunnel syndrome include:

- Numbness or tingling infingers or hand, especially in thumb, index finger, middle finger and ring finger
- A sense of weakness in hand and a tendency to drop things.

Complications

Loss of a limb Because nerve damage can cause a lack of feeling in feet, cuts and sores may go unnoticed and eventually become severely infected or ulcerated — a condition in which the skin and soft tissues break down. The risk of infection is high because diabetes reduces blood flow to feet. Infections that spread to the bone and cause tissue death (gangrene) may be impossible to treat and require amputation of a toe, foot or even the lower leg.[13]

Charcot joint This occurs when a joint, usually in the foot, deteriorates because of nerve damage. Charcot joint is marked by loss of sensation, as well as swelling, instability and sometimes deformity in the joint itself. Early treatment can promote healing and prevent further damage.[14]

Urinary tract infections and urinary incontinence Damage to the nerves that control bladder can prevent it from emptying completely. This allows bacteria to multiply in bladder and kidneys, leading to urinary tract infections. Nerve damage can also affect ability to feel when need to urinate or to control the muscles that release urine.

Hypoglycemia unawareness Normally, when blood sugar drops too low — below 70 milligrams per deciliter (mg/dL), or 3.9 millimoles per liter (mmol/L) — develop symptoms such as shakiness, sweating and a fast heartbeat. Autonomic neuropathy can interfere with ability to notice these symptoms.[15,16]

- **Low blood pressure** Damage to the nerves that control circulation can affect body's ability to adjust blood pressure. This can cause a sharp drop in pressure when stand after sitting (orthostatic hypotension), which may lead to dizziness and fainting.
- **Digestive problems** Nerve damage in the digestive system can cause constipation or diarrhea — or alternating bouts of constipation and diarrhea — as well as nausea, vomiting, bloating and loss of appetite. It can also cause gastroparesis, a condition in which the stomach empties too slowly or not at all. This can interfere with digestion and cause nausea, vomiting and bloating, and severely affect blood sugar levels and nutrition.

- **Sexual dysfunction** Autonomic neuropathy often damages the nerves that affect the sex organs, leading to erectile dysfunction in men and problems with lubrication and arousal in women.
- **Increased or decreased sweating**When the sweat glands don't function normally, body isn't able to regulate its temperature properly. A reduced or complete lack of perspiration (anhidrosis) can be life-threatening. Autonomic neuropathy may also cause excessive sweating, particularly at night or while eating.
-

Diagnosis

Diabetic neuropathy is usually diagnosed based on symptoms, medical history and a physical exam. **Filament test.** Sensitivity to touch may be tested using a soft nylon fiber called a monofilament.[17]

- **Nerve conduction studies.** This test measures how quickly the nerves in arms and legs conduct electrical signals. It's often used to diagnose carpal tunnel syndrome.
- **Electromyography (EMG).** Often performed along with nerve conduction studies, electromyography measures the electrical discharges produced in muscles.
- **Quantitative sensory testing.** This noninvasive test is used to assess how nerves respond to vibration and changes in temperature.
- **Autonomic testing.**If have symptoms of autonomic neuropathy, your doctor may request special tests to look at blood pressure in different positions and assess ability to sweat

Prevention

Blood sugar controlkeeping your blood sugar tightly controlled requires continuous monitoring and, if patient take insulin, frequent doses of medication. But keeping blood sugar consistently within target range is the best way to help prevent neuropathy and other complications of diabetes [18] Consistency is important because shifts in blood sugar levels produce damage

Foot care

- Foot problems, including sores that don't heal, ulcers and even amputation, are a common complication of diabetic neuropathy[19,20] But can prevent many of these problems by having a comprehensive foot exam at least once a year, having your doctor check your feet at each office visit and taking good care of feet at home. **Check your feet every day.** Look for blisters, cuts, bruises, cracked and peeling skin, redness and swelling. Use a mirror or ask a friend or family member to help examine parts of feet that are hard to see.
- **Keep your feet clean and dry.** Wash feet every day with lukewarm water and mild soap. Avoid soaking feet. Dry feet and between your toes carefully by blotting or patting with a soft towel.

  Moisturize feet thoroughly to prevent cracking. Avoid getting lotion between toes, however, as this can encourage fungal growth.

- **Trim your toenails carefully.** Cut toenails straight across, and file the edges carefully so there are no sharp edges.
- **Wear clean, dry socks.** Look for socks made of cotton or moisture-wicking fibers that don't have tight bands or thick seams.
- **Wear cushioned shoes that fit well.** Always wear shoes or slippers to protect your feet from injury.

Treatment

Diabetic neuropathy has no known cure. Treatment for diabetic neuropathy focuses on:

- Slowing progression of the disease
- Relieving pain
- Managing complications and restoring function.

Conclusion

This review comprises the importance of understanding the causes,symptoms,complications and management of Diabetic Peripheral Neuropathy (DPN)

Abstract

Prevention and early detection are major objectives in the control of the oral cancer burden worldwide. At the present time, screening of oral cancer and its pre-invasive intra-epithelial stages, as well as its early detection, is still largely based on visual examination of the mouth. There is strong available evidence to suggest that visual inspection of the oral mucosa is effective in reducing mortality from oral cancer in individuals exposed to risk factors.However is well known to be limited by subjective interpretation and by the potential, albeit rare, occurrence of dysplasia and early OSCC within areas of normal-looking oral mucosa. As a consequence, adjunctive techniques have been suggested to increase our ability to differentiate between benign abnormalities and dysplastic/malignant changes as well as to identify areas of dysplasia/early OSCC that are not visible to naked eye. These include the use of toluidine blue, brush biopsy, chemiluminescence and tissue autofluorescence. We conclude that available studies have shown promising results, but strong evidence to support the use of oral cancer diagnostic aids is still lacking.

Key Words: Oral cancer, Biopsy, Premalignant lesion

Introduction

The incidence of oral cancer is rising in most countries, especially in developing countries. In the general male population, oral cancer is the sixth most frequent cancer [1]. Squamous cell carcinoma (SCC) accounts for 95% of oral cancers, and it is associated with avoidable etiological risk factors. Familial history of oral cancer is also documented as a risk factor for SCC of the head and neck. It affects the tissue lining of the mouth which is perfectly visible to dentists during routine examination. Dentists being the first to encounter such changes in the oral cavity, have the responsibility to counsel, diagnose and treat the disease at initial stage. Most of the oral cancer arises from premalignant lesion and is usually Asymptomatic,routine dental screening is essential for early diagnosis. cancer lesions with immediate referral to a head and neck surgeon or cancer treatment canter for biopsy and treatment of cancer is the best way to manage such cases and proper screening for evaluation of metastasis to or in some cases from other sites like breast,pancreas etc.

Cancer of the head and neck (H&N cancer), including all oral, laryngeal and pharyngeal sites, is the sixth most common cancer, accounting for about 643 000 new cases annually [2]. About 40% of head and neck malignancies are known to be squamous cell carcinomas arising in the oral cavity . Oral cancer is largely related to lifestyle, with major risk factors being tobacco and alcohol misuse. In addition to smoking, the use of smokeless tobacco has been strongly linked to oral cancer. Carcinoma of oral cavity occur as a primary lesion which originates in any of the tissues in the oral cavity,either by metastasis from a distant site of origin, or by extending from a neighbouring anatomic structure, such as the nasal cavity.The oral cancers may originate in any of the tissues of the mouth, and may be of varied histologic types: teratoma, adenocarcinoma which are derived from a major or minor salivary gland, lymphoma from tonsillar or other lymphoid tissue, or melanoma from the pigment-producing cells of the oral mucosa. Oral or mouth cancer most commonly involves the tongue. It may also occur on the floor of the mouth, cheek lining, gingival(gums), lips, or palate (roof of the mouth). Less commonly other types of oral cancer occur, such as Kaposi's sarcoma[3]. Diagnostic tools and aids to diagnosis are discussed, as are treatment modalities. It is imperative that all dental professionals perform a simple head and neck examination in addition to an oral examination during each new patient visit and each six-month recall appointment. Early detection saves lives.This article reviews on various diagnostic aids for detection of oralcancer.In this review article we will be discussing about the various diagnostic aids present for detection of the oral cancer

Detection of Precancerous Stage

Early diagnosis of oral cancer patients would decrease mortality and help to improve treatment. Oral surgeons and dentists are the early diagnoses that diagnose these patients in early stages. Persons who deal with oral cancer such as healthcare providers, dental surgeons, and oral oncologist should have high knowledge and awareness that would help them to provide better diagnosis for oral cancer patients. The clinical significance of oral precancerous lesions lies in its association with malignant transformation into OSCC[4,5]. Only by histology the oral cancerous lesion can be diagnosed, although present as a spectrum of epithelial changes, rather than distinct categories. The World Health Organization in 2005 graded precancerous changes into mild, moderate, severe and carcinoma in situation.Precancerous lesion occur in oral cavity in three types.They are white,red and mix of white and red lesions.These conditions are known as leukoplakia which are white lesion or erythroplakia which are red lesions[6]. There are other pathological conditions that are considered precancerous including oral lichen planus and oral submucous fibrosis. The malignant potential of the above mentioned oral lesions cannot be accurately predicted solely on the basis of their clinical characteristics, histological evaluation is essential for all suspicious lesions. Unfortunately, histological findings only indicate that a given lesion may have malignant potential (dysplasia), and cannot be used for the prediction of malignant changes. Thus, the presence of dysplasia only indicates that an oral lesion may have an increased risk of malignant transformation[7]. Molecular biomarkers capable of identifying the subset of lesions likely to progress to cancer are being widely investigated including genetic and epigenetic alterations observed in oral mucosal precancerous lesions.

Investigations

Chest x-ray, CT or MRI scans, and tissue biopsy are some special investigations that are done during diagnosing oral cancer. There are a different types of screening devices that may help dentists in diagnosing oral cancer, including the Velscope, Vizilite Plus and the identafi 3000. There is no evidence that routine use of these devices in general dental practice saves lives. The most traditional type of biopsy is incisional. This is simply taking a small portion of the cancerous tissue for microscopic examnation. In an incisional biopsy, the doctor will remove part or all of the lesion depending on its size and his ability to define the extent of it at this early stage. In diagnosing the larger areas such as an enlarged lymph node, fine needle aspiration cytology (fine needle biopsy or FNB) has found an increasing role in

diagnosis[8,9] The technique is reliable and relatively inexpensive. In it, a syringe attached with a small needle is inserted into the questionable mass, and cells are aspirated, or pulled out into the syringe as the doctor draws back the piston of the syringe. Depending onplacement of the needle , as with all biopsies, the skill and experience of the pathologist who will be diagnosing the cells,the success will be determined . It is likely that the dentist will insert the needle and draw out cellular material from several different locations in the mass to ensure that a thorough and representative sample has been taken.

Non-Invasive Methods

Recent advancements in oral cancer research have led to the development of potentially useful diagnostic tools at the clinical and molecular level for the early detection of oral cancer. A non-invasive brush biopsy (BrushTest) can be performed to rule out the presence of dysplasia (pre-cancer) and cancer on areas of the mouth that exhibit an unexplained colour variation or lesion. While this has some usefulness in preliminary evaluation of a suspect area, it is not a standalone procedure, and if a positive find returns, this must be confirmed by a conventional incisional biopsy[10].

Other ways to determine the presence or extent of oral cancer exist. For instance, radiographs, also referred to as x-rays, can assist in determining the potential growth of a tumour into bone. While oral cancers unlike many other malignancies can usually be seen with the naked eye, some cancers are located internally in the body, making their detection difficult. Different scanning options, some of which assist in determining the presence of tumours or growths, and some of which can even detect malignancy, are necessary in these instances. CT O CAT and Magnetic Resonance Imaging (MRI), is helpful in providing accurate views of the affected area. Because cancer cells are dividing rapidly, they break down glucose much faster than normal cells. The increased activity will show up on a PET scan, and can indicate both primary and metastatic tumours. All these types of scans are still used largely for confirmation or measuring extent. Saliva from patients has been used in a novel way to provide molecular biomarkers for oral cancer detection. Saliva is a mirror of the body, reflecting virtually the entire spectrum of normal and disease states and its use as a diagnostic fluid meets the demands for an inexpensive, non-invasive and accessible diagnostic tool. Discovery of analytes in saliva of normal and diseased subjects suggests a very promising function of saliva as a local and systematic diagnostic tool. Toluidine blue (TB) is a member of the thiazine group of metachromatic dyes, which binds to DNA and is partially soluble both in water and in alcohol. Theoretically, dysplastic and malignant cells

have higher nucleic acid content than normal, and thus, staining of suspicious lesions with this dye can aid recognition of mucosal changes[11] TB has been used as a vital stain to highlight potentially malignant oral lesions[12].since the early 1980s. A positive staining of TB may appear as a dark royal blue. Recently, molecular studies on TB stained lesions reported a link between carcinoma and loss of heterozygosity at 3p and 17p, while dysplasia resulted in loss of heterozygosity at 9p. The presence of loss of heterozygosity has also been reported in high frequency of TB-stained lesions without or with low grade dysplasia[13]

Brush Biopsy

The oral brush biopsy, also known as OralCDx Brush Test system, consists of a method of collecting a trans-epithelial sample of cells from a mucosal lesion with representation of the superficial, intermediate and parabasal/basal layers of the epithelium[16]. This test was specifically designed to investigate mucosal abnormalities that would otherwise not be subjected to biopsy because of low-risk clinical features [17].A specially designed brush is the non-lacerational device used for epithelial cell collection and samples are eventually fixed onto a glass slide, stained with a modified Papanicolaou test and analyzed microscopically via a computer-based imaging system. Results are reported as "positive" or "atypical" when cellular morphology is highly suspicious for epithelial dysplasia or carcinoma or when abnormal epithelial changes are of uncertain diagnostic significance respectively. Results are defined as negative when no abnormalities can be found. The test is considered an intermediate diagnostic step as a scalpel biopsy must follow when an abnormal result is reported (atypical or positive).

Several studies have been performed in an attempt to test the sensitivity and specificity of brush biopsy in detecting dysplasia or OSCC. However, inconsistencies and potential bias of these studies have been reported by several authors[18].In the majority of studies for example, scalpel biopsy was performed after brush biopsy of lesions with high-risk clinical features, but not after brush biopsy of innocuously-looking lesions [18]. This is believed to alter results regarding sensitivity and specificity of the test in the clinical context where accuracy is much needed (diagnosis of those lesions that appear innocuous and would otherwise not be biopsied) and supports the criticism an intermediate non-diagnostic test would be superfluous when clinical features are highly suspicious for dysplasia/OSCC and a biopsy has to be performed anyway.

Indeedcurrent data show that OralCDx's cytologic test is highly sensitive and specific in detecting dysplastic changes in high-risk mucosal lesions (due to clinical findings suggestive of malignancy), but when used in a low-risk population with benign-appearing oral epithelial lesions, the accuracy is reduced and the rate of false-positive findings increases.
Further rigorous studies are needed to investigate the sensitivity and specificity of brush biopsy in detecting in low-risk populations with clinically innocuous lesions.

Toluidine Blue Staining

Toluidine blue (TB), also known as tolonium chloride, is a vital dye that is believed to stain nucleic acids. Hence, it has been used for many years as an aid to the identification of clinically occult mucosal abnormalities and as a useful way of demarcating the extent of a potentially malignant lesion prior to excision [19] Several studies on TB have been performed in the past years but the majority of them present significant limitations and methodological biases [18,19]. These have been reviewed in detail by Lingen and coworkers and include (i) absence of randomized controlled trials, (ii) absence of histological diagnosis as a gold standard, (iii) and variability in methods of application [20].

Analysis of current evidence suggests that TB is good at detecting carcinomas, but its sensitivity in detecting dysplasias is significantly lower. Furthermore, there remain a high percentage of false positive stains which impairs its use in primary care settings as a valid screening mean. In addition, controversy exists regarding the subjective interpretation of mucosal staining and criteria for positive results (e.g. dark royal blue versus pale blue staining) .

At present, TB is best used by experienced clinicians as an adjunct to clinical examination in the evaluation of the biologic potential of potentially malignant oral lesions. A recent study [21] showed that TB preferentially stained visible lesions with high risk molecular patterns and predicted risk and outcome in cases where little to no microscopic evidence of dysplasia was present. To date, however, research has not been extended to determine whether TB can identify and predict the risk of progression for epithelial abnormalities that cannot be seen with the naked eye.

Chemiluminescence

Clinical inspection of oral mucosa with the aid of chemiluminescent blue/white light was recently suggested to improve the identification of mucosal abnormalities with respect to the use of normal incandescent light[22].

The relevant technology (ViziLite system – Zila Pharmaceuticals, Phoenix, AZ), involves the use of an oral rinse with a 1% acetic acid solution for 1 minute followed by the examination of the oral mucosa under diffuse chemiluminescent blue/white light (wavelength of 490 to 510 nm). The theory behind this technique is that the acetic acid removes the glycoprotein barrier and slightly desiccates the oral mucosa, the abnormal cells of the mucosa then absorbing and reflecting the blue/white light in a different way with respect to normal cells. Hence normal mucosa appears blue, whereas abnormal mucosal areas reflect the light (due to higher nuclear/cytoplasmic ratio of epithelial cells) and appear more aceto-white with brighter, sharper and more distinct margins [23]

More recently, the ViziLite system was modified in order to include the use of TB and a new chemiluminescence device (MicroLux DL) was introduced.

Several studies have been performed with the Vizilite system with the attempt to demonstrate its efficacy in to enhance the identification of mucosal abnormalities. It should be highlighted that no study has demonstrated that the chemiluminescence can help in differentiating dysplasia/carcinoma from benign lesions. Hence, the majority of studies have investigated how chemiluminescence enhances subjective clinical evaluation of intra-oral lesions including brightness, sharpness and texture with respect to routine clinical examination .As these parameters are highly subjective, it is not surprising that results have been contradictory . Whilst some authors report that this technique can improve the detection of intra-oral abnormalities (regardless their nature), other reported that the overall detection rate was not significantly improved and the chemiluminescent light produced reflections that made visualization even more difficult than with incandescent light . Furthermore, the majority of the studies are limited by methodological flaws such as lack of histopathological diagnosis or clear objectives (screening device versus case-finding device) . Some studies suggest that chemiluminescence may help identifying occult lesions that cannot be seen with incandescent light but this, however, is not supported by any strong evidence [24].

Tissue Fluorescence Imaging

Tissue autofluorescence has been used in the screening and diagnosis of precancers and early cancer of the lung, uterine cervix, skin and, more recently, of the oral cavity. The concept behind tissue autoflorescence is that changes in the structure (e.g., hyperkeratosis, hyperchromatin and increased cellular/nuclear pleomorphism) and metabolism (e.g. concentration of flavin adenine dinucleotide [FAD] and nicotinamide adenine dinucleotide [NADH]) of the epithelium, as well as changes of the sub-epithelial stroma (e.g. composition of collagen matrix and elastin), alter their interaction with light [25] Specifically, these epithelial and stromal changes can alter the distribution of tissue fluorophores and as a consequence the way they emit fluorescence after stimulation with intense blue excitation (400 to 460 nm) light, a process defined autoflorescence. The autoflorescence signal is finally visualized directly by a human observer. With regards to the oral cavity, normal oral mucosa emits a pale green autofluorescence when viewed through the instrument handpiece whilst abnormal tissue exhibits decreased autofluorescence and appears darker with respect to the surrounding healthy tissue. Autoflorescence technology for inspection of the oral mucosa has been developed by LED Medical Diagnostics Inc.

Tissue Flouresence Spectroscopy

In addition to visual autofluorescence, a technique called autofluorescence spectroscopy has been recently tested in oral oncology research[26].The autofluorescence spectroscopy system consists of a small optical fiber that produces various excitation wavelengths and a spectrograph that receives and records on a computer and analyzes, via a dedicated software, the spectra of reflected fluorescence from the tissue . This technique has the clear advantage of eliminating the subjective interpretation of tissue fluorescence changes. However, the downside is that more variables (e.g. combination of wavelengths, methodology of fluorescence analysis etc) have to be tested and considered and this has led to controversial and often unclear results. Overall, autofluorescence spectroscopy seems to be very accurate for distinguishing lesions from healthy oral mucosa, with high sensitivity and specificity, especially when malignant tumors are compared to healthy mucosa. However, the ability of the technique to distinguish and classify different types of lesion has been reported to be low.Moreover autofluorescence spectroscopy is for practical reasons not suitable to detect new lesions or to demarcate large lesions as the optical fiber can sample only a small mucosal area. This limits the use of spectroscopy to the evaluation of a well defined small mucosal lesion that has been already identified through visual inspection, with the attempt to clarify its

benign or (pre)malignant nature. Further research is needed to support this clinical application of autofluorescence spectroscopy

Conclusion

The World Health Organization has clearly indentified prevention and early detection as the major targets in the battle to control the oral cancer burden worldwide (26) Prevention and early detection of Oral cancer and its pre-invasive intra-epithelial stages is still largely based on visual examination of the mouth, although a variety of molecular techniques have been tested and are likely to represent the ultimate goal of oral cancer research [27].Toluidine Blue has been used by clinicians for many years, yet a clear demonstration of TB indications, limitations, as well as strong evidence from methodologically sound clinical trials is still lacking. Brush biopsy is another example of promising novel diagnostic technique that unfortunately has not been supported by robust evidence. At present, the utilization of these techniques in clinical practice is largely anedoctal and is principally directed to help experienced clinicians at improving their ability to detect dysplasia and early Oral cancer in high-risk individuals attending secondary and tertiary centers.

Abstract

The term antibiotic associated diarrhoea (AAD) refers to a benign, self-limited diarrhoea following the use of antimicrobials. The prolonged use of multiple antibiotics, especially broad-spectrum group of antibiotics with poor intestinal absorption or high biliary excretion, induces a change in the composition and function of the intestinal flora thus resulting in AAD. Almost all antibiotics can result in the occurrence of AAD but few have a greater chance in doing so for example, Vancomycin, erythromycin and cephalosporins. The spectrum of manifestations in AAD ranges from normal diarrhoea to severe colitis. The main cause for AAD is the proliferation of Clostridium Difficile in intestinal flora. Apart from these bacteria, there are other bacteria which could cause AAD such as Staphylococcus aureus or Clostridium Perfringens. The occurrence of AAD is influenced by factors like nosocomial outbreaks, individual susceptibility and the pattern of prescription of the antibiotics. For the diagnosis of Clostridium Difficile associated diarrhoea stool samples can be taken for testing, colonoscopies can be taken to check for the presence of the bacteria and a blood test can be taken to test for leukocytosis which occurs during severe AAD.Diarrhoea is usually a symptom of a bowel infection [47]. Consumption of probiotics containing beneficial bacteria such as yeast, lactobacillus can help in curing AAD as they restore the healthy balance of the intestinal tract.

Key Words*:* *Antibiotic, Diarrhoea, Clostridium Difficile, Prophylaxis, Bacteria*

Introduction

The human body has a diverse assemblage of bacteria. Their symbiotic interaction have now been recognised as important predictors of human health. Abnormal communities are associated with complex diseases like obesity, irritable bowel syndrome. Administration of antibiotics disrupts the normal flora leading to diseases. Diarrhoea is a common adverse effect of antibiotic therapy and is characterised by mushy or watery stools. American Heart Association (AHA) and other committees of experts have proposed different guidelines and antibiotic prophylaxis regimens.

Organisms Which Cause AAD

There are various microorganisms which cause AAD like clostridium difficile, clostridium Perfringens, Staphylococcus Aureus, Klebsiellaoxytoca, salmonella species and candida species[2]. The most common organism being clostridium difficile. Infection with difficile is treatable.

Clostridium Difficile

Cl. difficile is an anaerobic, gram-positive spore forming bacillus first isolated in 1935 from faecal flora of healthy neonates. Spores of Cl. difficile may persist for many months in hospital wards and are particularly resistant to oxygen, desiccation and many disinfectants[3]. Pathogenic strains of Cl. difficile produce two major toxins: toxin A, an enterotoxin (308 kDa protein) and toxin B, a potent cytotoxin approximately 270 kDa protein. Both toxins are involved in the pathogenesis of Cl. difficile disease in humans. This toxigenic gram-positive bacillus is asymptomatically carried by 1%–3% of the human population, yet more prevalent in infants[4]. C.difficle is detected in 5% of stools or more healthy adults and upto 63% of patients without diarrhoea in hospital setup [5]. Asymptomatic carriers very rarely develop CDAD but they can contaminate the hospital environment [6,7]. This pathogen affects the non-hospitalisedpatientsfor whom the risk factors are antibiotic therapy, proton pump inhibitors, and also the use of receptor antagonists [8].

In the rectum and in the distal colon pseudomembranous colitis is fatal for 6%-30% cases [9]. These pseudo-membranes appear as yellow plaques which are easily visualized by colonoscopy. Almost all the antibiotics including vancomycin, Metronidazole and cancer therapy has been linked with CDAD and colitis [10, 11].

C.difficle releases two pathogenic strains with two major toxins: an Enterotoxin, toxin A and toxin B, a potent cytotoxin approximately with 270 kDA protein. Both these toxins are causative agents for C.difficle associated infections. Variety of genes in close proximity in bacterial genome encodes these toxins and they show only about 49% of structural homology[12]. Both the toxins activate cell-signaling molecules leading to production and also to the release of proinflammatory cytokines including interleukin-1, TNF- and interleukin-8 [13]. After internalization inside the host cell, toxin mediated glucosylation inactivates cellular rho proteins, that are essential for maintaining the actin cytoskeleton. This leads to the disorganization of colonocyte structure, disruption of protein synthesis, cell rounding and cell death [14].

Infants, mostly newborns, are colonized with C.difficle at the rate of 25-80% still most of them remain asymptomatic in spite the presence of toxin[15]. This is mostly due to immaturity of enterocytes with absence of toxin receptors expression[16]. Clinical presentation varies from asymptomatic carrier, diarrhoea, and colitis to PMC. Cl. difficile diarrhoea is associated with the passage of frequent loose stools along with mucus. Presence of visible blood is not much common. Leucocytosis is evident in stool. Anegative cytotoxicity test maybe performed, however, it does not completely rule out Cl. difficile because the cause of diarrhoea as 30% of patients may be missed, if toxin detection alone is employed [17]. Tests must be performed on fresh sample, because storage at ambient temperatures results in possible denaturation of toxin [18].

The standardised diagnostic test for Cl. difficile toxin in stool is the tissue culture cytotoxicity assay. It is 67 to 100% sensitive and 85-100% specific if it is performed correctly [19]. It can detect very little, like 10 pg of toxin B [15]. A variety of cell lines have been used by various workers, which include Vero, CHO, HEp2, MRC 526 etc. The main disadvantage is that it needs requires cell culture facility and requires incubation for 24-48 hrs. Counter current immuno electrophoresis has also been used in the past for direct detection of toxin B in stool [20]. Several commercial kits (EIAs) are available for detection of toxin A or both A and B in stool specimens.

Clostridium Perfringens

C. perfringens causes food poisoning and a different genotype has been implicated in causing AAD [21]. Clostridium perfringens type A is associated with 5-20% cases of antibiotic-associated diarrhoea (AAD) even though Clostridium difficile is implicated in the most severe cases[22]. Borriello et al, were the first to suggest that the association of C. perfringens with antibiotic treatment is causal rather than fortuitous [23]. They reported the prevalence of C. perfringens and its enterotoxin in 1.6% patients with Cl. difficile toxin positivity in 14.4% of their patients and 2/11 of them excreting both the organisms. Evidence supporting a causal role for C. perfringens in non-food borne diarrheal disease includes the presence of enterotoxin in the faeces of patients with AAD. Clostridium perfringens AAD is a distinct entity though it is unclear if antibiotic exposure primarily permits the proliferation of small numbers of resident C. perfringens strains or allows theiracquisition [24]. Clostridium difficile may account for only approximately 20% of all cases of AAD [24] and C. perfringens up to 15% [25].

Staphylococcus Aureus

Staphylococcus aureus was once thought to be a main cause of AAD, and was misdiagnosed for the clostridium difficile AAD infections [26].Certain studies provide evidence that enterotoxin-producing strains of methicillin-resistant S. aureus may cause nosocomial antibiotic-associated diarrhoea [27].

Klebsiellaoxytoca

K.oxytoca is considered an opportunistic pathogen and is now recognized as a clinically significant pathogen associated with nosocomial infections in hospitalized patients, including children and neonates [28][29][30].K. oxytoca also is purported to be an etiological agent of antibiotic-associated hemorrhagic colitis (AAHC) in adults and adolescents. AAHC patients develop clinical signs following antibiotic and/or anti-inflammatory therapy; these typically include bloody diarrhoea, severe abdominal cramping, and segmental hemorrhagic colitis as visualized by colonoscopy, most commonly in the ascending colon and the cecum [29][32][33].

Salmonella Species

S.newport was found which was multi drug resistant producing resistance to Ampicillin, Carbenecillin, and Methicillin etc was recently reported as a cause for AAD[34]. The patients who are taking antibiotic initially took this S.newport before taking the antibiotic and this S.newport selected the pathogenic resistance. Previously patients had even taking fluoroquinolone that has led to fluoroquinolone resistance enteric disease caused by Salmonella[35].Salmonella might even cause pseudo membranous colitis[36].

Candida Species

In patients those who are negative for Clostridium difficle, overgrowth of Candida species has been identified as the cause of AAD. Almost all of these patients respond to oral nystatin. [37].Lactose intolerance in rabbits is caused by candida which depresses the lactase activity in the rabbit's intestine, the net secretion of water, sodium; potassium in the ileum of rats is done by an endotoxin [38].

Diagnosis of the Main Causative Agents

Clostridium difficile causes mainly nosocomial enteric diseases that range from antibiotic-associated diarrhoea to pseudomembranous colitis (PMC) [39]. Various laboratory methods may be used to diagnose C. difficile associated diarrhoea and colitis (CADC), but the two main approaches currently available are based on detection of toxin A, toxin B, or both in stool specimens and detection of toxigenic strains after stool culture (toxigenic culture). For toxigenic culture, such an approach has been realized until now in only a few studies using both a toxin A enzyme immunoassay (EIA) and a cytotoxin assay [40-42].

The cytotoxin assay is considered the most sensitive method for detecting toxin B in stools, but it requires the use of cell culture and antitoxin and is not well standardized. This limits its use in many clinical laboratories. Commercially available rapid EIAs that detect both toxins have been shown to accurately detect toxins in stools and may represent a more practical method among diagnostic strategies that combine detection of toxins in stools with toxigenic culture[43].

An enzyme-linked immunoassay (ELISA) can be carried out for the detection of clostridium perfringens. Other non pathogenic species like Staphylococcus aureus species, Candida sp.

and Klebsiellapneumoniae can also be detected by ELISA. Pulsed-field gel electrophoresis (PFGE) can be used to detect S. aureus [44].

Treatment of AAD

Discontinuation of antibiotic therapy withdraws the offending agent but is often not appropriate if the indication for such therapy was correct. An alternative is to change the antibiotics to a low risk group for the induction of AAD (parenteral aminoglycosides, trimethoprim, rifampicin or a quinolone) [45].

The major form of intestinal disorders is the pseudomembranous colitis associated with Clostridium difficile which occurs in 10-20% of all AAD. In most cases of AAD discontinuation or replacement of the inciting antibiotic by another drug with lower AAD risk can be effective. For more severe cases involving C. difficile, the treatment of diarrhoea requires an antibiotic treatment, with glycopeptides (vancomycin) or metronidazole. Another approach to AAD treatment or prevention is based on the use of non-pathogenic living organisms, capable of re-establishing the equilibrium of the intestinal ecosystem. Several organisms have been used in treatment or prophylaxis of AAD such as selected strains of Lactobacillus acidophilus, L. bulgaricus, Bifidobacteriumlongum, and Enterococcus faecium[46].

Conclusion

A common complication of antibiotic use is the development of gastrointestinal disease. Comparative studies that use microbial ecology techniques to analyze temporally sampled patients and control individuals are promising approaches against AAD. Traditional culture-based methods continue to be the gold standard for disease diagnostics, but this approach can only detect organisms that are easy to isolate and have simple metabolic requirements. Since the vast majority of the human gut microbiota is currently non-cultivable, a nonculture-based approach may be more useful for the diagnosis and prediction of clinical outcomes. The key to addressing AAD is prompt diagnosis followed by effective treatment and institution of control measures. The prevalence of AAD in children is lower than that in adults. Majority suffer from mild illness. Further researches should be made on clinical treatments of AAD as it has been showing an increasing scale in the present scenario.

Abstract

Dental caries, a progressive bacterial damage to teeth, is one of the most commondiseases that affects 95% of the population and is still a major cause of tooth loss. Caries diagnosis - as an intellectual process - is the determination of the presence and extent of a caries lesion. Furthermore the judgement of its activity is an integral part of diagnosis.The most common method of caries detection is visual-tactile. Other non-invasive techniques for detection of early caries have been developed and investigated such as Quantitative Light-induced Fluorescence (QLF), DIAGNOdent (DD), Fibre-optic Transillumination (FOTI) and Electrical Conductance (EC). Based on previous systematic reviews, the diagnosis of NCCLs might be more accurately achieved in combination of the visual method and the use of other methods such as electrical methods and QLF for monitoring purposes.The use of technologies as adjunct to clinical visual examination for caries diagnosis will facilitate preventive care in dentistry to lower treatment cost as well as reduce the cost and time for testing potential anticaries agents. It also helps to know about the state of the art methodologies for the detection and assessment of early carious lesions. Therefore, this articles is provides an overview of various diagnostic aids used in modern dentistry.

Key Words:*diagnostic methods, early detection, caries, Biofilm, treatment*

Introduction

Mostprevalentdiseaseofmankind isdental carieswhich manifests from a range of microscopic to macroscopic changes that affects the surrounding vicinity of the tooth surface. Conventional examination of caries detection is based on visual examination and tactile

sensation aided byradiograph.Dental caries is a dynamic disease process, where early lesions undergo many demineralizationandremineralisation cyclesbefore being identifiedclinically.[1]Moreover , remaining caries after cavity preparation continues to be a great concern for most of the clinicians , as most of them are not sure about complete removal of residual caries . Infact , success of restorative procedure depends on complete removal of unhealthy tooth tissues. During the early stages of the disease , caries progression is reversible and converted from a active to an inactive state . Therefore ,accurate diagnosis before cavitation aids in preventive treatment such asfluoride application, pit and fissure sealants, significantly improves dental healthand reducing the need for extensive drilling and filling.[2] Conventionaldiagnosis of caries with subjective interpretation, visual examination and tactile sensation , aided by radiographs allows clinician to make a dichotomous decision . Many studies based on these conventional methods often shows that these methods has low sensitivity and high specificity, that is a large number of lesions may be missed out.So it apparent that conventional method of caries detection does not fullfill the criteria of an ideal caries detection methods. This criteria includes detection of caries at an earlier age,provide valid prospective caries risk assessment for different age groups and determine present caries activity and monitor lesions behaviour over time.The shortcomings with conventional method, facilitates the need for newer and supplementary caries detection aids.[3]

Mechanism of Caries

Increased intake of sucrose, in the presence of a biofilm creates an acidic environment in the immediate vicinity of the tooth structure. This is followed by the sequence of random biochemical reactions resulting in demineralization and remineralization of the tooth. However, as long as the dynamic equilibrium of mineral content of the tooth is maintained, the entire sequence remains within boundary of a physiological process. In the presence of factors disturbing the haemostasis the process of deminerization persists and prevents the reminerization process. In due of course of time this shift in the balance leads to more changes in the structure of tooth structure. Thus physiological caries process bomes pathological caries disease.

Examination of Caries Lesion

An diagnostic tool should have the ability to detect the presence or absence of caries It should be sensitive and specific enough to produce maximum number of true negative results than false neagtives and false positives to the minimum. Accurate interpretation of caries depends on many factors including attributes of the clinician, observation, knowledge, discipline etc. A diagnostic aid should be designed in such a way, so that it culminates in reliable, reproducible results, with minimal inter/ intra observer variation. It should also provide same accuracy, in detecting signs of varying severity on various surfaces such as occlusal, proximal and root surface. Also, a scale of measurement of diagnostic threshold should be present in an ideal diagnostic tool .However detection of carious lesion, scale of measurement differs with clinician, researches, gadgets and techniques. Therefore the current trend in caries diagnosis if focused on

a) Formulating diagnostic criteria that are realistic and useful for the treatment decision.
b) Evolution of technical gadgets which aims at lowering the diagnostic threshold in order to detect the earliest mineral loss.
c) Quantification of test results should be reduced , so that inter and intra observer variation associated with qualitative assessment
d) Dichotomous, nominal, ordinal scale used for caries detection should be shifted to a numerical scale therby monitoring the progress of the lesion over time.

Visual and Tactile Examination

It is accomplished using mouth mirror, sharp probe, 3in 1 syringe. It also requires good lightening, clean and dry tooth surface.This examination is primarily based on subjective interpretation of surface characteristics such as integrity, texture, translucency,location and colour[3].Presence of plaque, debris and other local factors should be checked to assess the texture of the enamel. Gingival and periodontal status is also assessed by the presence or absence of bleeding.[4] The enamel decalcification index was also used to determine the number of white spot lesions. But this method of examination is not as effective as advanced methods because of the spread of caries from one site to other site which leads to further spread of the disease. This method is widely used in clinics for detecting carious lesions on the entire surface. [5] But this method is not effective in detecting caries in the relatively advanced stage,involving one third or more of the thickness.[6] Major drawback in this

conventional method of caries detection is use of various diagnostic criteria used by various authors. There have also been controversies whether to probe or not. However from many studies it has been resurged as an valuable adjunt in the visual examination of caries. However probing is limited to removal of plaque from the surface of an incipient lesion, thereby enhancing visibility. Probing is also used to assess the surface texture of a lesion. In this method blunt probe is manipulated at an anle of 20- 40 degree angle to the surface of the tooth. Blunt probing is recommended against a sharp probr acting perpendicular to the tooth surface

Nyvad's System

Reliable system for assessment of cavitated and noncavitated lesion is Nyvaad system. In this method, accumulation of biofilm is used as an indicator of caries activity and also sharp dental probe is used to assess surface roughness .In modern dentistry, Nyvaad system is modified with the adoption of ball ended probe , which is gently run across the surface in order to assess its texture and also to remove biofilm . However important aspect of caries detection is that surface must be dry because saliva can mask differences in the reflection of light between carious and healthy tooth structure , therby hindering the observation of changes in color and brightness on the enamel surface.[7]

Radiograph Techniques

Radiographic techniques are based on the fact that as caries progress there will be decrease in the mineral content of enamel and dentine , results in decrease in the attenuation of X ray beam as it passess through the teeth . This feature is being recorded in the image receptor as increase in radiographic density.[7]

Conventional Radiography

Bitewing radiography came into practise in 1925, play a role in clinical examination of proximal and occlusal caries lesion in dentine. This method has more sensitivity and provides enhanced estimation of lesion depth than the visual inspection.This method is preferred over periapical radiograph mainly because of the superior imaging geometry for visualizing caries. Bite wing requires 40 -60% of tooth calcification is required to produce the radiographic

image.Bitewing radiograph has a tendency to make false positive results due to Mack band effect. Mach band effect is a phenomenon in which there is enhancement of contrast dark and relatively light area. This ultimately results in dark band being sharply demarcated radiolucency in the dentino enamel junction.Another effect called cervical burnout is wrongly interpreted as cervical caries, when a collar or wedge shaped radiolucency occurs between bone height and cement enamel junction, there occurs an optical illusion phenomenon.[7] Due to this, there is variability in the penetration of X- rays at the cervical region of the tooth and also in the regions above and below it .This results in the dark shadow in the radiograph due to lower absorption of photons in the cervical region of tooth. This necessitates the fact that the radiographic images should be interrupted with caution, requiring constant retraining, updating, experience and also should be accompanied other supplemental caries detection aids .[8]

Digital Radiography

Digital radiography has more advantages than conventional radiography.This includes image acquisition,since the image is displayed immediately after exposure and no processing has to performed.Reduction in radiation dose is another advantage of this method.It is comprised of number of pixels and produces instant and constant images. Each pixel has a value in the range betwee 0 and 255 , with 0 representing back and 255 representing white . The values in between represents shades of grey .Concerning assessment of small proximal caries digital radiography has low specificity and sensitivity compared to conventional methods .No dark room needed.Reduced dose of radiation.Eliminates hazards of film development. Capable of tele transmission.Major disadvantages include high cost and reduced life expectancy of chip.Digital radiography has replacing traditional analogue or screen film systems. It uses the principle of conversion of x ray energy into digital signals using scanning laser stimulating illuminescence.[9]

Digital Image Enhancement

It is a more advanced image analysis tools.It is used to detect small differences between subsequent radiograph that would have remaind unobserved , because of over projection of anatomical structures[7].This procedure is based on the principle that the two radiographic

images obtained at different time intervals, with the same projection geometry, which is alligned by using specific software.Resolution of unedged radiograph is lower when compared to enhanced radiograph .Contrast of the image can be enhanced by a mathematical rule which is decided by algorithm/ filter.They are not practically used because they are very time-consuming.[10]

Digital Substraction Radiography

In this method ,a digital bitewing radiograph is taken and later a second radiograph of exactly the same region is produced with identical exposure time, tube current, and voltage. By subtracting,gray values for each coordinate of the firstradiograph from equivalent coordinate of second, a subtraction image is obtained .If there is no changes , the result of subtraction is zero .Nonzero result will be obtained in case of onset or progression of demineralization. It has been used in the assessment of progression , arrest ,or regression of of caries lesion. Due to difficulty of image visualisation, this method is not routinely applied in clinical detection of caries.[11]

Tuned Aperture Computed Tomography

This method is used to visualize radiographic section through teeth. Then the sectioned slices can be viewed for the presence of radiolucency.It is used to detect small caries and even secondary caries.But this method is technique sensitive.Once the exposure begins , the tube and film move in opposite direction through a mechanical linkage.Image of objects in the focal plane remain in fixed positions on radiographic films and are clearly imaged[12] .Images of objects located outside focal plane are continuouslybeing changing their positions on the film .As a result , images of these objects are blurred beyond recognition by motion unsharpness.Advantage of this system over other system is that,images produced less superimposition of anatomic noise over the area of interest.Radiation of Tuned Aperture computer Tomography is 1-2 times less than that of a conventional periapical xrayfilm . So that the total exposure dose is divided amongst the series of images taken . It is most suitable for detecting vertical root fractures .

Enhanced Visible Techniques

i) Fibre Optic Transillumination (FOTI)

The differential transmission of light through healthy tooth structure as compared to carious tooth structure can be detected by using quantitative fibre optic transmission and digital image fibre optic trans illumination .Operator is able to use a more focused and higher intensity light beam instead of an operatory light , which increases the potential to detect smaller carious lesions .[11] This system has a built-in CCD camera to allow for image capture of the tooth . By illuminating teeth with this system . Areas of demineralized enamel or dentin scatter light and incipient caries appear darker in the resultant image . In this method photon energy is converted to electric energy by using receptors with photon cells .[12] This is then transmitted to a video processor and converted into color value and displayed on video monitor .In early days , this method is used for the detection of approximal lesions in the anterior teeth but later its use was extended to detect proximal lesions in the posterior teeth as well . [13]

I) Digital Imaging Fiber Optic Transillumination

Short coming perceived in FOTI lead to the development of (DIFOTI) . In this method images of the teeth are obtained by using visible light via fiber optic transillumination . These images are acquired by digital electronic CCD camera . This method is used to enhance the contrast between sound and carious tissues and to quantify features of incipient , frank, and secondary lesions on occlusal , approximal and smooth surface and also changes in the coronal tooth structure such as tooth fractures and fluorosis. It has high specificity when compared to radiography .[14]

Quantitative Laser Induced Fluorescence

It provides a fluorescent image of a tooth surface within yellow- green spectrum of visible light that is used to quantify mineral loss and size of the lesion . It is also used to detect enamel caries in visually inaccessible areas . This system consists of a micro video ccd camera ,measurement probe, control unit , and computer fitted with a frame grabber .The control unit consists of an illumination device and imaging electronics . Light source is a special arc lamp based on xenon technology .[15] Fluorescent image is recorded with yellow

transmitting filter positioned in front of the CCD sensor.Appearence of red fluorescence indicates leaking around restorations and sealants . It is emitted by porphyrins metabolised by bacteria dental bio film , calculus, or an infective carious lesion . In this method first lesion is detected by the examiner and subsequent capturing the image of the lesion .Quantitative analysis of the image is done . Finally long term monitoring of the lesion is done . In a study done by Beerens MW et al , to compare discrimatory power of caries assessment using QLF and digital radiography after de bonding of orthodontic appliance ,it was shown that standardized oral photographs were equally useful to detect changes in caries severity and outperformed ICDAS.[16] In a study done by Mariana et al to review the application of QLF for quantitative assessment of early enamel lesions showed that , because of this property associated with high reliability values and a video repositioning software , which facilitates the acquisition of identical images on different occasion ; this device is an excellent method for monitoring enamel caries lesions to assess whether preventive measures are able to arrest or remineralize the lesion.[17] Advantage of this method is that image can be stored and can be used to motivate patients to seek healthcare and also to prevent dental disease through routine preventive care . A study done by Eggertsson et an demonstrates various applications of quantitative laser fluorescence which includes dectection of primary, secondary , root caries on smooth and occlusal surface in both primary and permanent teeth; detection of remineriliza tion around orthodontic appliance ; monitoring demineriliation and remineriliation caries lesion ; quantifying dental plaque ; erosion and fluorosis ; detection of extrinsic stains .[18]

Laser Induced Fluorescence

i) **Diagnodent**:

Diagnosis of occlusal caries in adjunct to visual and radiographic examination .DIAGNOdent system is a part of exciting new generation of dental equipment . It uses infrared laser fluorescence f 655 nm for the detection of occlusal and smooth surface caries . It uses a simple laser diode to compare the reflection wavelength against a well-known healthy baseline to uncover decay. Carious tooth structure exhibits fluoresce proportionate to the degree of caries , resulting in elevated scale readings on the display . [19] The unit has a fiber- optic cable that transmits light source to a handpiece that contains a fiber- optic eye in the tip . First , the laser diode is aimed at the healthy enamel tooth structure to obtain a

benchmark reading . After calibration , it is moved to inspect all the surfaces of the teeth , shining the laser at 2.5 mm into all suspected areas . As the laser pulses into grooves , fissures , and crackes, it redirects fluorescence light with particular wavelength . This is because light is absorbed by the organic and inorganic components of the tooth which induce infrared fluorescence . This fluorescence is collected at the top of handpiece and transmitted back to the DIAGNOdentunit . Light is measured by receptors , converted into an acoustic signal , and evaluated electronically to reveal values between 0 and 99.The intensity of the fluorescence depends upon the wavelength of the light as well as the structure and condition of hard dentinal tissues . Factors such as the presence of bacterial plaque , dental prophylactic pastes , fissure sealants , and composite resin materials give false positive readings with this instrument . In a study done by, Ava valisichani et al to evaluate diagnostic value of diagnodent in detecting caries under composite restoration it was reported that diagnodent has higher positive and negative prediction value compared to radiograph . These findings along with higher sensitivity and specificity has proven that diagnodent is most accurate in detecting secondary caries under primary molar restoration, compared to radiograph.[20]Diagnodent pen is the recent modification of diagnodent which has the tip of 0.4mm therby facilitating easy placement in approximal areas for the detection of incipient proximal caries . Diagnodent may show errors in the presence of stains , biofilm and filligs but still has advantage in monitoring the progression or regression of incipint lesion over time .

Ultra Sound Caries Detection

Use of ultrasound to detect dental caries has been proposed for the past 30 years , but the technique has received renewed interest particularly in the past 10 years. It was introduced for detecting early carious lesions on smooth surface .Demirelizationof natural enamel is assessed by ultrasound pulse- echo technique .[21] It is observed that there is a definite correlation between the mineral content of the body of the lesion and the relative echo amplitude changes . Ultrasound makes the use of sound waves with frequency . They are longitudinal or pressure waves which travel through gasses , liquids , and solids . Ultrasound interacts differently with different tissues .They have a frequency of > 20,000 Hz and have all the properties of waves , in that they may be scattered, refracted , or absorbed . The

relative ability of a medium to reflecting sounds on its mechanical properties such as elasticity , density , and wavelength of sound . Amount of sound detected provides information about the structure of reflecting interface , whereas the time taken for sound to be reflecting provides information about the position of the reflecting interface . Sound waves produced as a result of minute changes in crystal dimension may be omitted continually , as burst of waves or as a single pulse .

Mechanism of Action

For sound waves to reach the tooth , they have to travel through a coupling medium or an agent which has acoustic impedance . Various acoustic coupling agents have been used such as mercury ,aluminum rods , water , and glycerine .An ultrasonic probe is used which sends and receives longitudinal waves to and from the surface of the tooth . [22] Initial white spot lesions produce no or weak surface echoes , whereas sites with visible cavitation produce echoes with substantially higher amplitude .[23]This method if improved can be a realistic alternative to radiographic diagnosis of caries on approximal surfaces . It is also more sensitive than visual-tactile method .

Conclusion

The devices vary in their modes of action as well as their capability as caries diagnostic aids . Difference in caries presentation and behaviour in different anatomical sites make it unlikely that any one of the diagnostic aids will have adequate sensitivity and specificity of detection of carious lesions for all sites ; a combination of diagnostic tools will help us diagnose lesions earlier and detect failing restorations as early as possible .

Distalization Method in Correction of Class II Malocclusion-A Review

Jaseera Banu.K [1], Saravana Pandian[2], Padma Ariga[3]
Graduate Student[1] ,Reader[2], Department of orthodontics

Abstract

Class II malocclusion is one of the most difficult malocclusions to treat, and stationary anchorage is one of the main factors determining the success of the treatment. Maxillary molar distalization, a common treatment modality used to correct Class II malocclusions, is particularly indicated when maxillary skeletal or dentoalveolar protrusion is present. Using intraoral appliances, maxillary molars can routinely be moved distally with little or no patient cooperation. One factor that influences the movement rate is the type of movement and another factor is the timing of treatment.The correction of Class II malocclusions has been hampered by the use of appliances which require the patient to co-operate with headgear, elastics, or the wearing of a removable appliance. 'Non-compliance therapy' involves the use of appliances which minimize the need for such co-operation and attempt to maximize the predictability of results. The treatment effects of extra oral forces in the correction of Class II malocclusions are well known. Although headgear use is usually inevitable in subjects with maxillary excess, co-operation problems seem to be a challenge for orthodontist.The present article explains about different modality of distalization methods in correction of class II malocclusion.

Key Words:*Malocclusion, distalization, removable appliance, head gear, anchorage.*

Introduction

Orthodontic problems can be classified either as skeletal problems or dental problems. Skeletal problems can be originated from skeletal deviations and treated with orthopaedic appliances, fixed mechanics, or surgery. Dental problems are classified as dental class I malocclusion, dental class II malocclusion, and dental class III malocclusion [1]. Dental class II malocclusion is generally caused by the early loss of the upper deciduous second molar. After early tooth loss, upper first permanent molars erupt more mesially than their normal locations or drift mesially [2]. The traditional approach to distalize molars, especially in the maxilla, is extra oral traction[3].

Patient's cooperation is a determinant factor for successful orthodontic treatment, thus, protocols that require minimal collaboration are of great value in orthodontic practice. Intraoral distalizersfulfil this function, i.e., they correct Class II malocclusion without entirely depending on the patient to achieve satisfactory results by the end of treatment [4]. The success of molar distalization has been reported to depend on two main factors: a] the type of movement and [b] the timing of treatment. It has been noted that distalization of the first molar occurs by tipping rather than by bodily movement [5].

Class II malocclusion is one of the most common problems encountered in orthodontic practice today. Advances in mechanotherapy and changes in treatment concepts and philosophies now minimize the need for extractions in mild to moderate discrepancies [6]. Non-extraction treatment of class II malocclusions, which are characterized by the absence of skeletal involvement, frequently requires distal driving of maxillary molars into a class I relationship. Several intraoral distalizing appliances have been introduced to eliminate the need for patient cooperation. The distal jet is a palatally placed, intra-arch maxillary molar distalization appliance [7].

Nonextraction treatment of Angle Class II malocclusion usually requires distalization of maxillary molars. Beginning in the 1980s, intraoral appliances, such as repelling magnets, 1superelastic NiTi coil springs, pendulum, Jones jig and distal jet, have been introduced to distalize molars with minimal patient compliance. Intraoral distalization appliances have been designed to deliver a continuous reciprocal force on the maxillary first molars. Any action to move molars distally produces a mesial reaction force on the anchoring teeth. As a consequence, if the premolars or incisors [or both] are the anchoring teeth, they move mesially, the incisors protrude, and overjet increases [8].However, this effect is in

contradiction with the main objective of Class II treatment. Furthermore, distalized molars are questionable anchors for the retraction of premolars and incisors, despite attempts [headgears, Nance appliance etc] that have been made to maintain them in their new positions.

The creation and use of intramaxillary intraoral appliances for molar distalization in Class II malocclusion have been made possible through advancements in biomechanics and technology and materials that have allowed the delivery of light and constant forces over a wide range of deactivation. The application of force in these appliances can occur from the buccal region, the palatal region, or both [9]. The forces applied can involve friction [sliding mechanics], as with the use of nickel-titanium [NiTi] coil springs, or they can be friction free, as when the pendulum appliance is used. When the efficiency of these different categories of appliances is compared, it is not clear which ones are associated with the largest molar distalization and which produce the smallest quantity of undesirable adverse effects, such as loss of anchorage and molar tipping [10].The aim of the study is to review the distalization method in correction of class II malocclusion.

Anchorage

Anchorage, defined as a resistance to unwanted tooth movement, is a prerequisite for the orthodontic treatment of dental and skeletal malocclusions. Its role in orthodontic treatment was appreciated early on, as prominent orthodontists such as Gunnell, Desirabode, and Angle realized the limitations of moving teeth against other teeth used for anchorage, introducing ideas such as the use of occipital, stationary, and occlusal anchorage [11].Controlling anchorage helps to avoid undesirable tooth movements. However, even a small reactive force can cause undesirable movements; it is important to have absolute anchorage to avoid them. Absolute or infinite anchorage is defined as no movement of the anchorage unit [zero anchorage loss] as a consequence to the reaction forces applied to move teeth [12]. Such an anchorage can only be obtained by using ankylosed teeth or dental implants as anchors, both relying on bone to inhibit movement. Anchorage provided by devices, such as implants or miniscrew implants fixed to bone, may be obtained by enhancing the support to the reactive unit [indirect anchorage] or by fixing the anchor units [direct anchorage], thus facilitating skeletal anchorage [13].

Types of Anchorage

Skeletal anchorage devices can be classified into 2 main categories, based on their origin.The first category has its origins in osseointegrated dental implants and includes the orthodontic mini-implants, the retromolar implants, and the palatal implants. The second category finds its origin in the surgical mini-implants, such as the one used by Creekmore and Eklund and those described later by Kanomiand Costa et al [14].The main differences between the 2 categories are that devices of the second category are smaller in diameter, have smooth surfaces, and are designed to be loaded shortly after insertion. In a similar manner, Cope classified the current available methods of skeletal anchorage as either biocompatible or biologic in nature [15]. The biologic group included ankylosed and dilacerated teeth, whereas the biocompatible group included temporary anchorage devices. He further subclassified both groups based on the manner in which they are attached to bone into biochemical [osseointegrated] or mechanical [16].

Various Methods of Distalization

Distalization procedures are aimed at moving the molars in a distal direction so as to gain space. Distal movement of maxillary molars in individuals with class2 malocclusion and moderate space deficiency in upper arch can be achieved by extra oral traction or by a combination of extra oral traction and removable appliance [17].It can be brought about by either extra oral or intra oral methods.

Extra oral methods include usage of head gears whereas intra oral methods includes open coil springs,intra oral magnets,Sagittal appliance and pendulum appliance. The treatment of Class II malocclusion without extractions usually requires patient compliance, either for bodily distalization of molars [headgear] or for distalization of molar roots after use of intraoral distalizing appliances [pendulum].Intraoral distalization through intraoral fixed appliances is only the first phase of treatment that will be finalized with fixed corrective mechanics [18].

In recent years, clinical interest has focused in particular on the different pendulum appliances. The aim of molar distalization should be maximum bodily tooth movement, on the one hand to minimize the risk of root resorption and on the other to permit subsequent bodily retraction of the anterior dentition. The standard pendulum appliance introduced by Hilgers. However, gives rise to the appliance-specific fundamental problem that once the

activated pendulum springs have been inserted into the palatal sheaths of the molar bands, the molars are moved in an arc on pendulum like radii. The potential consequences are palatal movements of the molars and tipping of the dental crowns [19].

HEAD GEAR-as an Extra Oral Distalizer

Extra oral headgear traction, which has been used since the 1800s, is the oldest and most commonly used method to correct a Class II buccal segment relationship by restricting forward growth of the maxilla and/or distalizing the maxillary molars [20]. Despite its efficacy, headgear treatment is dependent on patient co-operation. Furthermore, the difficulty of use and aesthetic concerns make patient co-operation difficult to maintain throughout treatment [21]. In comparison with headgear, intraoral molar distalization methods are easier to use, more socially acceptable for patients, and the distalization time is shorter because they apply continuous forces. However, they have several disadvantages such as mesialization of the maxillary premolars, protrusion of the maxillary incisors, an increase in overjet, and anchorage loss [22, 23].

Fig 1 :Headgear

Pendulum Appliance

Distalization of maxillary teeth with the pendulum and presumably increasing mandibulargrowthwiththeHerbstappliance are two treatment options for correction of class II malocclusion[24].The investigators, however, found no differences in mandibular growth between groups, although they noted slightly greater increases in lower anterior facial height

[LAFH] in the pendulum group. Treatment success with both appliances occurred primarily from dentoalveolarchanges [25].In 2008, Angelieri et al proposed that the pendulum appliance produced only dentoalveolar effects, while the CHG appliance, which restricted maxillary forward displacement, improved the skeletal maxillomandibular relationship. [26]

The pendulum appliance consists of an anterior Nance portion with an expansion screw and two posteriorly extending TMA coil springs that were recurred at the end where they fit into lingual sheath. Using a composite resin and auxiliary wires, the appliance was bonded to the maxillary premolars or molars, avoiding occlusal interferences [27].The pendulum springs were activated 45 degree in the centre of the helices on the Sagittal plane with an initial force of 200-250 g. Depending on the molar movement required, activation was repeated intra orally once or twice during the treatment [28].

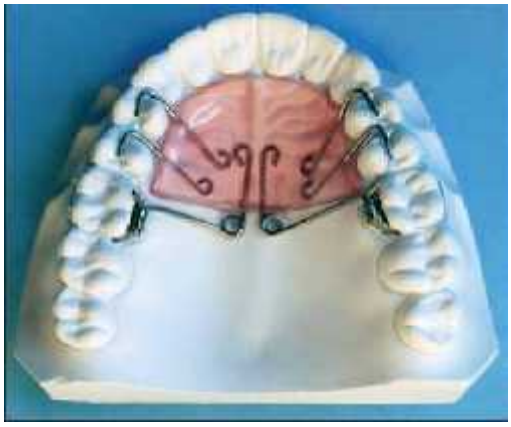

Fig 2:Pendulum Appliance

Nickel-Titanium Coil Springs

Nickel titanium coil springs have been used in conjugate with various non compliance appliances to produce rapid maxillary molar movements, because it was found that they have greater spring back and super elastic properties than stainless steel coils. Furthermore, the most important reason for their implementation in noncompliance distalization devices is their ability to exert a very long range of constant, light and continuous force [29].

Open coil springs are commonly used in orthodontic practice; but there have been few experimental studies on their clinical effects. Chaconas et al. [1984] investigated the effects of wire thickness, length and radius of open coil springs on the forces produced. It was found that more linear force was produced in open coil springs with a large lumen and in order to obtain an optimum force, open coil springs had to be compressed by about a third of its original length, producing a force value of between 270 and 540 g [30].

In 1988, Miura et al. [1988] compared the mechanical properties of Japanese nickel-titanium and stainless steel coil springs, in both closed and open types. They found that Japanese nickel-titanium coil springs exhibited superior spring-back and super elastic properties. Additionally, it was shown that the load value of super elastic activity could be effectively controlled by changing the diameter of the wire, the size of the lumen, the Martensitic transformation temperature, and the pitch of the open coil spring. The most important characteristic of Japanese nickel-titanium alloy coil springs was the ability to exert a very long range of constant, light, and continuous force [31]. Gianelly et al. [1991], obtained an average of 1–1·5 mm molar distalization in one month by 8–10 mm activation of super elastic nickel-titanium coil springs. To maintain anchorage, a modified Nance appliance was cemented to the upper first premolars [32]. An additional means of anchorage reinforcement involved the incorporation of uprighting springs to tip the crowns of these teeth distally and as a result, effective molar distalization was obtained. In cases with second molars in total occlusion, the use of Class II elastics was recommended to avoid anchorage loss [33]. Fraunhofer et al. [1993] compared nickel-titanium coil springs with stainless steel coil springs. These authors concluded that the light and continuous forces necessary for optimum tooth movement could be produced by means of nickel-titanium coil springs [34].

Fig 3: Nickel Titanium coil spring

Distal Jet Appliance

The distal jet is one of the more commonly used “noncompliance appliances” for molar distalization. It is a fixed lingual appliance that can produce bilateral or unilateral molar distalization in permanent as well as mixed dentition. The appliance consists of a bilateral piston and tube system with the tube embedded in an acrylic button in the palate, supported by attachments on the maxillary second premolars [35]. A distal jet appliance consists of an

acrylic Nance button and stainless steel wires. The appliance can easily be converted to a Nance appliance when the distalization is complete. A study done by karamanet al, concluded that the implant supported modified distal jet appliance is an effective and reliable method for distalizing maxillary molars, and this treatment requires minimal patient compliance [36].

Among the aforementioned appliances, the distal jet, a lingual distalization appliance, is said to feature several distinct advantages. The maxillary molars are distalized with less distal tipping and without the lingual movement that occurs with the pendulum and the distal jet can be easily converted into a Nance holding arch to maintain the distalized molar position [37].

The distal jet with full fixed brackets produces less molar tipping than other intraoral alternatives such as the pendulum, Jones jig, Greenfield molar distalizing appliance and the sagittal appliance. These studies also suggest that mild increases in lower anterior facial height are related to the amount of molar tipping generated during distalization. Perhaps appliances with better control of molar inclination [eg, distal jet] might diminish the risk, however small, of clinically significant vertical change [38].

To reduce anchorage loss, Gianelly et al recommended that molar distalization be performed before the eruption of the maxillary second molars. Several investigators, however, have found no difference in distalization and anchor- age loss for the pendulum, Jones jig, and distal jet when second molars were unerupted or erupted [39].Bussick and McNamara,Huerter, and Chiu discovered a mild increase in the mandibular plane angle during distalization when second molars were erupted. In contrast, Huerter described less anchorage loss when the second molars were completely erupted. The effect of the eruption status of second molars on distalization is inconclusive [40].

Fig 4: Distal Jet Appliance

CarriereDistalizer

The CarriereDistalizer is a simple-to-use device that is inconspicuous enough to promote patient acceptance and compliance. Loss of anchorage has not been a significant problem, although several techniques, including mini screws, are available for anchoring the Class II elastics[41].The CarriereDistalizer is designed to create a Class I molar and canine relationship. This appliance can be used as a first phase treatment in Class II cases with fully erupted first molars [42].

Fig 5: Carriere Distalizer

First Class Appliance

The first class appliance [FCA; Leone, Firenze, Italy] was proposed as an intraoral device that allows rapid distal movement of the maxillary molars [43]. A study done by Fortini et al proved that FCA produced rapid molar distalization: bilateral Class II molar relationship was corrected in 2.4 months on average. He also suggest that no significant changes in sagittal or vertical skeletal relationships were observed [44].Another study done by Papadopoulos et al, suggested that even though it shows a distalization without distal rotation and extrusion of the molars and with minimal, non significant proclination of the incisors it shows side effects similar to those produced with other noncompliance distalization appliances [45].

Fig 6: First Class Appliance

Keles Slider

In 2000, Keles and Sayinsu developed the intraoral bodily molar distalizer [IBMD] for molar distalization. Their results showed that the molars distalized without tipping; however, anchorage loss also occurred [46].In 2002 Keles et al, in his study provedthat theKeles Slider is an effective appliance to bodilydistalize molars. Class I molar relationships can be established in a short period of time, and there is little anchorage loss in comparison with the other intraoral distalization mechanics. The appliance is effective in deep bite correction. TheKeles Slider can also be used for correction of unilateral Class II molar relationships [47].

Fig 7: Keles Slider

Skeletal Anchorage System

Introduction of skeletal anchorage in orthodontics not only has allowed the simplification of many procedures conventionally employed for the control of anchorage, but also has reduced the undesirable effects of many appliances [48]. Moreover, miniscrews present many advantages, including low cost, low invasive insertion procedures, and great versatility: many authors have demonstrated that they can be used as a successful source of anchorage during orthodontic therapy [49]. In addition, miniscrews can be used in children, in adolescents, and in adults for different orthodontic procedures such as distalization, retraction of maxillary anterior teeth, intrusion, and protraction of maxillary posterior teeth and remain almost stationary throughout orthodontic loading, if they have been correctly positioned.

A skeletal anchorage system [SAS] has been developed that uses pure titanium anchor plates and screws as absolute orthodontic anchorage units[50].The anchor plates are mono cortically placed at the piriform opening rim, the zygomatic buttresses, and any regions of the mandibular cortical bone. SAS enables the rigid anchorage that results from the osseointegration effects in both the anchor plates and screws [51].Sugawara et al, used a

specially designed skeletal anchorage system [SAS] for correction of anterior open bite by intruding the mandibular molars in humans [52].

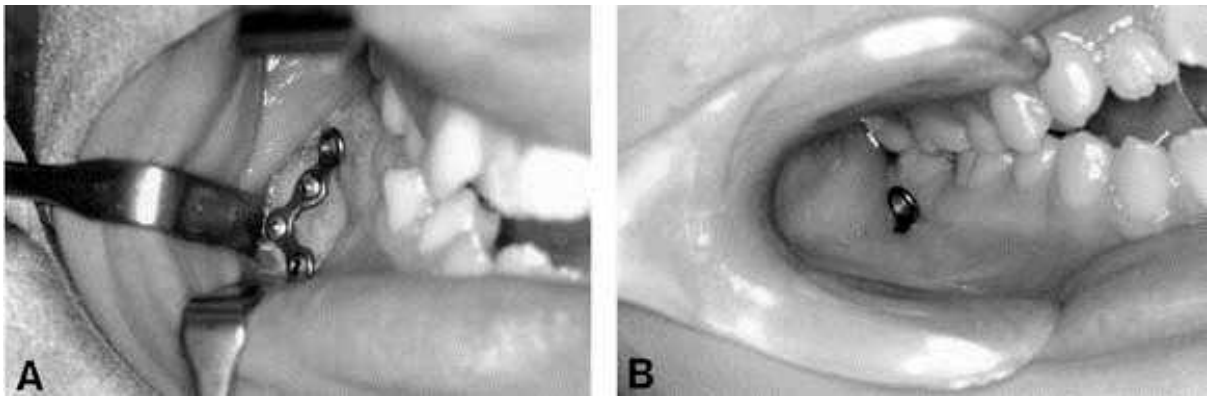

Fig 8: Intraoral Skeletal Anchorage System

Frozat Appliance

A modification of the Frozat [fixed Crozat] appliance initially developed by Mayes, the unilateral Frozat appliance consists of two molar bands soldered to a .038" Blue Elgiloyor .040" stainless steel wire [53]. Kinzinger et al, in his study suggested that unilateral Frozat appliance allows a controlled uprighting and distalization of the lower molars. Intramaxillaryanchorage is achieved by simultaneously inserting a rigid and passive buccal wire segment [54].

Fig 9: Frozat Appliance

Repelling Magnets

Magnets were introduced as a force system a few years before the introduction of super elastic coils. Ithas been shown that approximately one-half of the distal movement of molars treated with magnets are related to tipping, with the obvious risk of relapse[55].Bondemark et al, suggested that the super elastic nickel titanium open coils are more effective than the repelling samarium-cobalt magnets for simultaneous distal movement of maxillary first and second molars. He also says that the force applied by coils are more constant when compare to magnets [56].

Due to the increasing tendency towards non-extraction treatment, much work has been put into developing new intra-oral molar distalization procedures, including the use of magnetic forces and nickel-titanium coil springs. With their excellent properties, such as high energy product values and high coercive forces, rare earth magnets have been used in orthodontic tooth movements [57]. An important disadvantage of rare earth magnets is their low corrosion resistance, but by means of stainless steel coatings, the resistance against corrosion is increased.

Various investigators have studied the biological effects of static magnetic fields on living tissues. Changes in osteoblastic and osteoclastic activities, a decrease in epithelial thickness and an increase in blood flow rate have been accepted by several investigators as the biological effects of magnetic fields [58]. However, there is no agreement as to whether the effects reported were produced by the magnetic alloy or the magnetic field. In two different studies, Gianelly et al. achieved effective molar distalization using repelling magnets. They suggested weekly activation of the magnets in order to maximize the force and stated that in cases with second molars in complete occlusion, distalization took longer. Anchorage loss in this study was calculated as 20 per cent [59].

In another study by Itoh et al, also have used repelling magnets for molar distalization; they recommended activation of the magnets at intervals of 2 weeks and reported an anchorage loss of about 30 per cent. Using repelling magnets, Bondemark and Kurol [1992], reported effective molar distalization, together with distobuccal rotation [60].

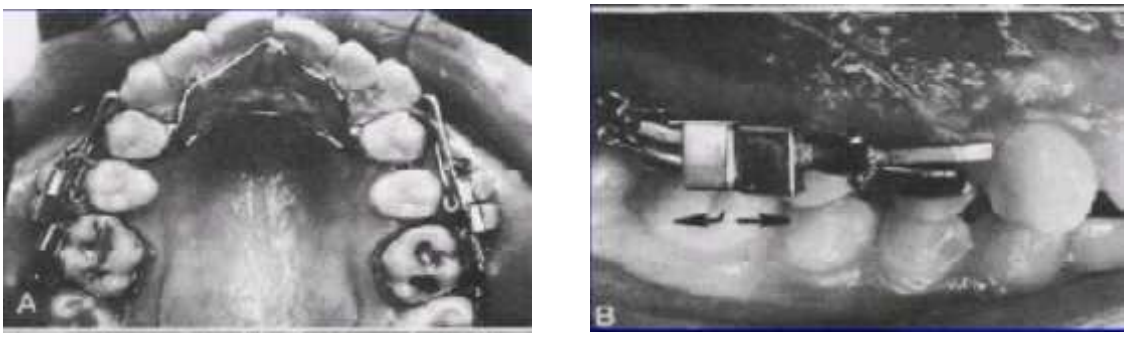

Fig 10: Intraoral Repelling Magnets

Frog Appliance

One of the important goals of molar distalizing therapy is to obtain bodily tooth movement of the molars with minimal rotation and distal inclination. TheFrog appliance was positioned approximately 10 to 12 mm apically to the occlusal surface of the maxillary molar with parallel orientation to the occlusal plane in our case. In this manner, a vector of effective force passing through the centre of resistance of the first molar was obtained [61].

In 2006, Walde developed an intraoral molar distalizing appliance named the Frog appliance [62].The Frog appliance consists of a special distalizing expansion screw with an anterior activation head that can be easily reached intraorally; additionally, a wired spring is attached to the expansion screw and is inserted into the palatal tubes of the molars [63].Mehmet et al,suggested that the Frog appliance is an effective and reliable method for the distalization of maxillary molars. Unfortunately, reciprocal anchorage loss in the premolars and incisors occurred during distalization [64].

Fig 11: Frog Appliance

Essix Based Molar Distalization

A new thermoplastic appliance called EssixH [RaintreeEssix, Inc., 4001 Division St, Metairie, LA 70002, USA] was first introduced as a retainer by Sheridan and colleagues in 1993 [65]. Thermoformed Essix appliances have multiple uses in general dentistry and orthodontics, which greatly expand the many treatment options currently available. Essix appliances are clear plastic; the result is aesthetically pleasing to the eye [66].Essix retainer proved to be sufficient for maintaining orthodontic treatment results [67]. The expected increase of occlusal contacts was not observed at the end of the retention period with Essix thermoplastic retainers as these cover the occlusal surfaces of teeth [68].

Fig 12: Essix Retainer

Mini Implants

Terms such as mini-implants, miniscrews, micro implants, and micro screws have been used to describe devices of skeletal anchorage. Although the group of these terms describes devices smaller than conventional dental implants that provide skeletal anchorage which is discontinued after treatment, they should not be used interchangeably. Implants and mini-implants refer to systems, which by definition imply that osseointegration sets in prior to loading, whereas screws to self-tapping devices that may be used without the condition of osseointegration. However, since 2004 it was agreed on that the word mini-implant should be applied both to palatal implants, to mini-implants, to miniscrews, and to micro screws [69].

Conclusion

Distalization represents an important constituent of non-extraction treatment in orthodontics. Molardistalization is recommended for class II malocclusion with skeletal and dentoalveolar maxillary protrusion or when the dental extraction is not recommended for

the maxillary. Distalization is the first phase treatment in correction of class II malocclusion. Molardistalization can be made unilaterally as well, in order to correct a unilateral class II relation.

Abstract

Replication of DNA – deoxyribonucleic acid – happens before a cell divides to ensure that both cells receive an exact copy of the parent's genetic material. While there are many similarities in how prokaryotic and eukaryotic cells replicate their DNA, there are several distinctions between them, due to the different size and complexity of the molecules, including the time it takes to complete the process.Prokaryotic cells are quite simple in structure. They have no nucleus, no organelles and a small amount of DNA in the form of a single, circular chromosome. Eukaryotic cells on the other hand, have a nucleus, multiple organelles and more DNA arranged in multiple, linear chromosomes.Replication of DNA is essential for the propagation of life. It is somewhat surprising then that, despite the vital nature of this process, cellular organisms show a great deal of variety in the mechanisms that they employ to ensure appropriate genome duplication. This diversity is manifested along classical evolutionary lines, with distinct combinations of replicon architecture and replication proteins being found in the three domains of life: the Bacteria, the Eukarya and the Archaea. Furthermore, although there are mechanistic parallels, even within a given domain of life, the way origins of replication are defined shows remarkable variation.

Keywords: DNA, Replication, Bacteria, Eukarya, Archaea.

Introduction

DNA replication is the way toward creating two indistinguishable reproductions from one unique DNA particle. This natural procedure happens in every single living creature and is the reason for organic legacy. DNA is comprised of two strands and each strand of the first DNA particle fills in as layout for the creation of the correlative strand, a procedure alluded to as semiconservative replication[1]. Cell editing and mistake checking systems guarantee close ideal constancy for DNA replication in a cell, DNA replication starts at particular areas, or inceptions of replication, in the genome. Loosening up of DNA at the inception and union of new strands brings about replication forks becoming bidirectional from the birthplace. Various proteins are related with the replication fork which helps as far as the start and continuation of DNA amalgamation. Most unmistakably, DNA polymerase incorporates the new DNA by adding reciprocal nucleotides to the layout strand. DNA replication can likewise be performed in vitro (falsely, outside a cell). DNA polymerases disconnected from cells and fake DNA preliminaries can be utilized to start DNA union at known successions in a format DNA atom. The polymerase chain response (PCR), a typical research facility method, consistently applies such simulated blend to open up a particular target DNA section from a pool of DNA.

DNA or deoxyribonucleic corrosive is a kind of particle known as a nucleic corrosive. It comprises of a 5-carbon deoxyribose sugar, a phosphate, and a nitrogenous base. Twofold stranded DNA comprises of two winding nucleic corrosive chains that are contorted into a twofold helix shape. This turning enables DNA to be more reduced. Keeping in mind the end goal to fit inside the core, DNA is pressed into firmly curled structures called chromatin. Chromatin gathers to shape chromosomes amid cell division. Preceding DNA replication, the chromatin extricates giving cell replication apparatus access to the DNA strands[2].

Replication of DNA – deoxyribonucleic corrosive – occurs before a cell partitions to guarantee that the two cells get a precise of the parent's hereditary material. While there are numerous similitudes in how prokaryotic and eukaryotic cells repeat their DNA, there are a few qualifications between them, because of the distinctive size and intricacy of the particles, including the time it takes to finish the process[3]. Prokaryotic cells are very straightforward in structure. They have no core, no organelles and a little measure of DNA as a solitary,

roundabout chromosome. Eukaryotic cells then again, have a core, various organelles and more DNA masterminded in different, straight chromosomes.

Arrangement of DNA replication

Stage 1: Replication Fork Formation

Before DNA can be repeated, the twofold stranded particle must be "unfastened" into two single strands. DNA has four bases called adenine (A), thymine (T), cytosine (C) and guanine (G) that shape combines between the two strands. Adenine just combines with thymine and cytosine just ties with guanine. Keeping in mind the end goal to loosen up DNA, these associations between base sets must be broken. This is performed by a compound known as DNA helicase. DNA helicase disturbs the hydrogen holding between base sets to isolate the strands into a Y shape known as the replication fork. This territory will be the layout for replication to begin[4].

DNA is directional in the two strands, connoted by a 5' and 3' end. This documentation connotes which side gathering is appended the DNA spine. The 5' end has a phosphate (P) amass joined, while the 3' end has a hydroxyl (OH) gather appended. This directionality is vital for replication as it just advances in the 5' to 3' course. In any case, the replication fork is bi-directional; one strand is situated in the 3' to 5' course (driving strand) while the other is arranged 5' to 3' (slacking strand). The two sides are along these lines recreated with two unique procedures to oblige the directional contrast.

Stage 2: Primer Binding

The main strand is the least difficult to repeat. Once the DNA strands have been isolated, a short bit of RNA called a groundwork ties to the 3' end of the strand. The groundwork dependably ties as the beginning stage for replication. Preliminaries are produced by the protein DNA primase.

Stage 3: Elongation

Proteins known as DNA polymerases are capable making the new strand by a procedure called extension. There are five diverse known sorts of DNA polymerases in microscopic organisms and human cells. In microorganisms, for example, E. coli, polymerase III is the primary replication compound, while polymerase I, II, IV and V are in charge of mistake checking and repair. DNA polymerase III ties to the strand at the site of the groundwork and starts adding new base sets corresponding to the strand amid replication[5]. In eukaryotic cells, polymerases alpha, delta, and epsilon are the essential polymerases associated with DNA replication. Since replication continues in the 5' to 3' bearing on the main strand, the recently shaped strand is consistent.

The slacking strand starts replication by authoritative with different preliminaries. Every preliminary is just a few bases separated. DNA polymerase at that point includes bits of DNA, called Okazaki sections, to the strand between preliminaries. This procedure of replication is broken as the recently made sections are disconnected.

Stage 4: Termination

Once both the nonstop and irregular strands are framed, a catalyst called exonuclease expels all RNA preliminaries from the first strands. These preliminaries are then supplanted with proper bases. Another exonuclease "edits" the recently framed DNA to check, evacuate and supplant any errors[6]. Another protein assembled DNA ligase joins Okazaki sections framing a solitary brought together strand. The finishes of the straight DNA introduce an issue as DNA polymerase can just add nucleotides in the 5′ to 3′ heading. The finishes of the parent strands comprise of rehashed DNA successions called telomeres. Telomeres go about as defensive tops toward the finish of chromosomes to keep close-by chromosomes from intertwining. A unique kind of DNA polymerase chemical called telomerase catalyzes the union of telomere arrangements at the closures of the DNA.Once completed, the parent strand and its complementary DNA strand coils into the familiar double helix shape. In the end, replication produces two DNA molecules, each with one strand from the parent molecule and one new strand.

Steps in DNA replication

DNA replication starts at a particular spot on the DNA atom called the birthplace of replication. At the starting point, catalysts loosen up the twofold helix making its segments open for replication. Each strand of the helix at that point isolates from the other, uncovering the now unpaired bases to fill in as layouts for new strands. A little section of RNA – ribonucleic corrosive – is included as a preliminary, at that point new nucleotide bases that supplement the unpaired bases can be gathered to shape two girl strands by each parent strand. This get together is expert with catalysts called DNA polymerases[7]. At the point when the procedure is finished, two DNA atoms have been framed indistinguishable to each other and to the parent particle.

Replication starts at specific positions in chromosomes called "causes" where assigned initiator proteins tie to DNA to begin the procedure of replication. There are imperative contrasts among microbes, archaea, and eukaryotes in this procedure, however there are likewise numerous striking similitudes that recommend the procedure goes back to the last all inclusive cell ancestor[8]. Microscopic organisms regularly contain just on chromosome with one beginning at which two replication forks gather and move inverse way. In spite of the fact that not all microorganisms take after this worldview, this is the situation for the Escherichia coli round 4.4 Mb genome, shaping a solitary replicon or unit of replication from a solitary source. At a rate of 1 Kb/s for each fork, this genome is reproduced inside 30 min. Interestingly, eukaryotes ordinarily have numerous direct chromosomes, each with numerous birthplaces. Numerous causes are a need for eukaryotes as they have substantially bigger genomes than microscopic organisms and eukaryotic replication forks move around 20 times more gradually than bacterial replication forks. For instance, the biggest human (chromosome #1) is 250 Mb and on the off chance that it had just a single starting point, it would require over 50 days to imitate contrasted with the regular 24 h division time of an eukaryotic cell and roughly 8 h for duplicating DNA in S stage. Start at every birthplace produces two disparate DNA replication forks along the chromosome to make a replicon that is copied just once per cell division. The duplication of numerous replicons in the long run yields two girl chromosomes assembled sister chromatids that are fastened until the point that they isolate amid mitosis. Albeit few archaea species have been described, they seem, by all accounts, to be transformative cross breeds amongst microbes and eukaryotes, since a few species have a solitary chromosome with a solitary cause, though different species have numerous starting points per chromosome. Besides, the ploidy of the genome in archaea shifts impressively,

with a few species having a 1C– 2C dispersion all through their cell cycle, while others have up to 25 duplicates of their genome in multiplying cells. The rate of DNA replication fork movement likewise has all the earmarks of being in the middle of that in microscopic organisms and eukaryotes, at around 20 kB/min, ∼10 times quicker than that in eukaryotes. Albeit a few microbes like E. coli duplicate their genomes significantly quicker, others, for example, Caulobacter crescentus reproduce at generally an indistinguishable rate from some archaea, for example, Pyrococcus abyssi.

Bacterial starting points are very much characterized groupings to which the replication initiator proteins tie. Conversely, eukaryotic starting points are not regularly characterized at the level of DNA arrangement (with the vital special case of the sprouting yeast Saccharomyces cerevisiae). Noteworthy late advance has demonstrated that eukaryotic beginnings are characterized less by DNA grouping than by chromatin association, with numerous roots relating to locales of DNA with transcriptional action or different highlights that enable access to starting point restricting proteins. Numerous human cell sources happen in successions that are developmentally moderated among vertebrates, recommending that they are a long way from arbitrary[9] . In many eukaryotes, a little subset of potential sources is utilized as a part of an average cell cycle in singular cells, however birthplace use can be extraordinarily expanded to encourage incredibly fast cell division, as found in the treated eggs of numerous creatures. Regardless of whether a birthplace is utilized or not is a stochastic procedure that relies upon the chromatin setting and now and again the formative condition of cells in multicellular life forms. Moreover the numerous beginnings in eukaryotic chromosomes are sorted out into bunches that are initiated at particular circumstances amid S period of the cell cycle, and the transient designing shifts again with formative designing of cells.

To start the way toward actuating a birthplace for replication, bacterial, archaeal, and eukaryotic cells utilize source restricting proteins made out of AAA+ family subunit(s). AAA+ proteins for the most part work as multimeric machines. For instance in microbes, various duplicates of the DnaA birthplace restricting protein shape a helical fiber that ties the beginning. The DnaA fiber ties ATP to loosen up an A/T-rich locale of the starting point, bringing about a solitary strand DNA (ssDNA) "bubble" onto which the replicative helicase loads[10].

Eukaryotes contain a six subunit beginning restricting protein alluded to as ORC (birthplace acknowledgment complex). Five of the ORC subunits are identified with AAA+ proteins and together with another AAA+ protein called Cdc6 that is profoundly related in grouping to the biggest ORC subunit, Orc1, they frame a ring-molded hexamer that ties DNA . Be that as it may, not at all like bacterial DnaA, ORC does not loosen up DNA at districts to which it ties. Archaeal cells additionally utilise AAA+proteins that are identified with the biggest subunit of ORC, Orc1 and to Cdc6, yet the quantity of these subunits changes relying upon the specific sort of archaeal cell. Both DnaA and ORC are utilized as a part of different procedures other than replication.

Replication mechanism

Replication is performed by a multiprotein replication machine that incorporates both little girl duplexes all the while. Replication machines have a similar centre parts in all cells: DNA polymerases, round sliding clips, a pentameric clasp loader, helicase, primase, and SSB (single-strand restricting protein). The manner by which these proteins are masterminded and interface with each other contrasts among cell types[11,12]. The replication machine is regularly alluded to as a "replisome." The bacterial replisome, is sorted out by the clasp loader, which contains three indistinguishable τ subunits that predicament three C-family DNA polymerase III (Pol III) polymerases. The τ subunit additionally ties the homohexameric helicase (i.e., E. coli DnaB). As primase shapes RNA groundworks, the cinch loader over and over burdens new roundabout β braces onto the preliminary/layout for use by the slacking strand Pol III(s). This primase/polymerase switch is encouraged by SSB, which ties ssDNA and empowers the cinch loader to unstick primase from the prepared site. SSB shields the ssDNA from nucleases and encourages prolongation by Pol III-β on ssDNA. The bacterial replisome is exceedingly processive, implying that in E. coli it can incorporate ~86 kb on the main strand without separating from the format. In any case, high processivity is a weakness on the slacking strand, which is blended as various short ~1000 nt Okazaki parts and requires the polymerase to separate from the format DNA and reassociate at another prepared site for each Okazaki section. To conquer this "processivity obstruction," particular systems have advanced that pry the polymerase from the cinch to discharge an Okazaki piece, on which the polymerase reassociates with another clasp at the following RNA prepared site.

The three Pol IIIs in the bacterial replisome help the generation of different Okazaki fragments[13].

Albeit eukaryotic and archaeal replisomes have comparative parts, the associations among the segments are very not the same as bacterial replisomes. The hexameric MCM2-7 circles the main strand, not the slacking strand and needs the Cdc45 and GINS proteins for it to work in loosening up DNA[14]. Additionally, the eukaryotic replisome contains two diverse B-family polymerases that capacity independently for the main and slacking strands, Pol ε and Pol δ, individually, notwithstanding Pol α/primase, which begins each Okazaki section. The slacking strand is covered by replication protein A (RPA), a heterotrimer SSB that is fundamentally and practically comparable to the bacterial SSB tetramer. As in microbes, a primase/polymerase switch is intervened by RPA. Both Pol ε and Pol δ work with a ring-molded multiplying cell atomic antigen (PCNA) clasp of comparable structure to E. coli β. PCNA is collected on DNA by the pentameric replication factor C (RFC) brace loader, made out of subunits with succession homology and comparative structure to the bacterial cinch loader. Dissimilar to microbes, RFC does not seem to contact the polymerases or the helicase, and the associations among replisome segments stay indistinct. There are various competitors among the numerous proteins known to be required for proficient eukaryotic replication that have no homolog in microorganisms. For instance, the GINS heterotetramer and the Cdc45 protein that shape a complex with the MCM2-7 helicase to yield the CMG complex may tie Pol α/primase. GINS and Cdc45 are required for proficient DNA loosening up movement and may tie different factors notwithstanding the MCM2-7 complex to compose the replisome. In growing yeast, a replication movement complex has been distinguished containing potential connections between the CMG and Pol α/primase by means of Ctf4/AND-1, and amongst CMG and Pol ε through Mrc1/Claspin. Point by point confirm for these and other conceivable associations, the elements of closely resembling proteins in different eukaryotes, and their significance for fork movement can be found.

The oligomeric structures of sliding cinches empower different proteins to tie one clasp at the same time, alluded to as the "toolbelt" hypothesis[15]. An extraordinary case is an archaeal PCNA heterotrimer in which each unique subunit ties an alternate accomplice protein (i.e., polymerase, ligase, and Fen1) that is associated with the amalgamation and development of

Okazaki pieces. These highlights of sliding cinches are talked about , however one angle will be said here as it has critical ramifications for replisome structure and capacity. Specifically, all phones contain an assortment of low-loyalty DNA polymerases that can sidestep injuries in the DNA, alluded to as "TLS" Pols (translesion blend polymerases). Distinctive Pols can tie the clip all the while and exchange places with each other, making the replisome a considerably more unique machine than initially thought , E. coli contains three "translesion" DNA polymerases (TLS Pols), which are instigated on DNA harm. Studies have demonstrated that at high fixations, for example, those instigated on DNA harm, the TLS Pols tie the β clip and exchange places with Pol III at a moving fork, yet hold the helicase to shape a "TLS replisome." TLS replisomes move significantly more gradually than Pol III and manage the speed of the helicase. A conspicuous preferred standpoint of shaping TLS replisomes on DNA harm is to moderate the replication fork, giving time for DNA repair before a replication fork experiences a sore. In the occasion a sore is experienced, it can be circumvent by the TLS polymerase.

Bacteria

In bacteria the origin of replication is named oriC, and commonly a solitary beginning exists for every bacterial chromosome. In Escherichia coli, oriC is situated between the gldA and mioC qualities. The % 250 bp oriC locale contains numerous rehashed groupings containing a nine base match accord component named the DnaA box[5,6]. Other microbes additionally have single starting points of replication with different DnaA boxes albeit both the exact number and conveyance of these crates change between species. Strikingly, in numerous microorganisms the cause of replication is discovered contiguous the quality for DnaA itself, recommending a system for the organize control of birthplace action and levels of initiator proteins. An individual accord DnaA box is bound by a monomer of the DnaA protein and this association actuates a sharp twist in the coupling site. In any case, in characteristic bacterial starting points there are various DnaA boxes and these arrange complex coopererative restricting occasions to DnaA boxes with changing degrees of adjustment to the agreement sequence[16,17]. An especially intriguing consequence of this is a DnaA box with poor preservation to the accord will most likely be unable to tie DnaA all alone. In any case, authoritative to this 'feeble' site can be encouraged by official of DnaA to a nearby high

partiality agreement site. Bacterial starting points of replication additionally have a moment monitored component, an exceedingly AT rich area. The loosening up of this naturally meltable DNA is a key advance in replication start at roots. Under very characterized in vitro conditions, DnaA is equipped for intervening halfway loosening up of this locale all alone. It shows up thusly, that the blend of DNA bowing initiated by DnaA and the agreeable connections between DnaA monomers on DNA result in nearby topological pressure that shows itself by loosening up of this naturally less steady district of duplex.

Eukaryotic sources

The recognisable proof of start destinations in eukaryotic creatures has been a burdensome errand. As opposed to the single, plainly characterized locales of bacterial replication, eukaryotic DNA union begins from hundreds or even a huge number of birthplaces, which once in a while contain evident arrangement themes, and are regularly hard to characterize[17] . This many-sided quality is intensified by the way that eukaryotic birthplace actuation is non concurrent. What's more, start site use shows significant adaptability under changing development conditions, or all through various phases of advancement. In later years, it has turned out to be progressively evident that epigenetic factors represent the direction of eukaryotic source activity[18]. These tweaks give the versatility important to composed start from different locales.

Archaea

Rather than the abundance of sub-atomic, hereditary and biochemical detail that is currently thought about roots of replication and their association with initiators in microorganisms and eukaryotes, next to no is thought about the sub-atomic premise of replication start in the third space of life, the archaea. It is entrenched that archaea have a captivating mix of bacterial and eukaryotic highlights and in addition viewpoints that are special to this space of life[19,20,21]. Archaeal chromosomes look like those of most microscopic organisms, being little, round and having polycistronic interpretation units. What's more, archaea are probably going to have coupled interpretation and interpretation. Notwithstanding, it has turned out to be evident that the centre data preparing apparatuses of the archaea are in a general sense

identified with those of eukaryotes. Accordingly, the interpretation and DNA replication apparatuses of archaea are firmly identified with, however altogether less difficult than, their eukaryotic partners and particular from those of microscopic organisms. There-fore, archaea introduce themselves as a conceivably straightforward model framework to comprehend the rationed occasions in DNA replication. Various investigations have portrayed the biochemical properties of archaeal DNA replication proteins[19]. It is likewise of impressive enthusiasm to see how the straightforward bacterial-like chromosomes of the archaea are repeated by an eukaryotic-type replication contraption, to clarify the idea of the archaeal replicon association , and to build up the instruments by which archaeal replication birthplaces are characterized.

Conclusion

Replication of DNA is basic for the spread of life. It is fairly shocking then that, regardless of the indispensable idea of this procedure, cell living beings demonstrate a lot of assortment in the systems that they utilise to guarantee fitting genome duplication. This assorted variety is showed along established transformative lines, with unmistakable blends of replicon engineering and replication proteins being found in the three spaces of life: the Bacteria, the Eukarya and the Archaea. Moreover, despite the fact that there are unthinking parallels, even inside a given area of life, the path causes of replication are characterized demonstrates noteworthy variety.

In prokaryotic cells, there is just a single purpose of source, replication happens in two restricting ways in the meantime, and happens in the cell cytoplasm. Eukaryotic cells then again, have various purposes of cause, and utilise unidirectional replication inside the core of the cell. Prokaryotic cells have maybe a couple sorts of polymerases, while eukaryotes have at least four.

Replication likewise occurs at a substantially speedier rate in prokaryotic cells, than in eukaryotes. A few microorganisms take just 40 minutes, while creature cells, for example, people may take up to 400 hours. What's more, eukaryotes likewise have an unmistakable procedure for duplicating the telomeres at the closures of their chromosomes. With their

roundabout chromosomes, prokaryotes have no finishes to incorporate. Ultimately, the short replication in prokaryotes happens constantly, yet eukaryotic cells just experience DNA replication amid the S-period of the cell cycle.

Abstract

Drug eluting stents were first developed in an attempt to prevent or address the issue of restenosis. Drug eluting stents consists of three parts namely, a stent platform, a coating of polymer that binds the drug to the stent and releases the drug and the stent itself.

The basic mechanism of drug delivery from a drug eluting scaffold involves encapsulating a drug in a polymer that either allows the drug to diffuse outward from it or that undergoes degradation in order to release the drug directly. For long term effects, non -biodegradable stents are the most commonly used stents. There are a wide variety of stents available and they are used for different purposes and procedures in the field of medicine. Vascular and biliary stents, expandable coronary stents and there are also simple plastic stents which is used to allow the flow of urine between kidney and the bladder. Drugs such as dexamethasone, betamethasone, heparin, hirudin, tocopherol, angiopeptin are delivered via stents.

Key Words: *Drug delivery, drug eluting stents, eluting agents, scaffold, non-biodegradable,*

Introduction

In general, the term stent is used to refer to a metal or a plastic tube which is inserted into the lumen of an anatomic vessel or a duct to keep the passage open during which the procedure is done. The term 'stenting' is used to refer to the procedure which involves the placement of these stents. Drug eluting stents consists of three parts namely, a stent platform, a coating of polymer that binds the drug to the stent and releases the drug and finally, the stent itself[1].The first procedure to treat blocked coronary arteries was coronary artery bypass graft surgery (CABG), in which a section of vein or artery from anywhere else in the body is used to bypass the diseased segment of coronary artery. In 1977, Andreas Grüntzig introduced PTCA which stands for percutaneous transluminal coronary angioplasty which is also called as balloon angioplasty, in which a catheter tube has been introduced through an artery, preferably a peripheral artery in the body and a balloon is expanded to bring the dilated narrowed segment of the artery back to normal size [2].As the equipment and techniques were improved, the use of PTCA increased by many folds, and by the mid-1980s, PTCA and CABG were both being performed at almost comparable rates and frequencies throughout the world[3].Balloon angioplasty was generally effective and safe, but restenosis which means a chance for the vessel to dilate once again was very much frequent, occurring in about 30– 40% of cases, which usually occurs within the first year after the process of dilation. In almost around 4 to 5% of balloon angioplasty cases, the dilation process may fail as a whole and acute or threatened closure of the coronary artery which can often be because of the dissection which has been prompted by an emergency CABGs [4].Two medical professionals namely, Dotter and Melvin Judkins suggested using prosthetic devices inside the arteries in the legs to maintain proper blood flow after the dilation process as early as the 1960s[5].In the year 1986, two medical professionals namely, Duel and Sigwart made a great breakthrough in the field of prosthetic stent placement by implanting the first ever coronary artery stent in human trials. This was done in the early 1990s and it showed the superiority of stent placement over theballoon angioplasty process. Restenosis was greatly reduced because of the fact that the stent acted as a scaffold to hold open the dilated segment of artery; acute closure of the coronary artery and also the requirement for emergency CABG was greatly reduced, because the stent repaired dissections of the arterial wall.

There are a wide variety of stents available and they are used for different purposes and procedures in the field of medicine. Vascular and biliary stents, expandable coronary stents and there are also simple plastic stents which is used to allow the flow of urine between

kidney and the bladder. These types are the most frequently used types of stents in the field of medicine.

- **Coronary Stents**

  Coronary stents are made of metal and will consist of three parts, an inflated balloon with a drug coated stent, a stent delivery catheter and a location marker. Coronary stents are used during an angioplasty procedure. It is also called as a percutaneous coronary intervention. Coronary stents are most commonly placed inside a coronary artery. Inside these coronary arteries, three types of stents can be placed. It can either be a drug eluting stent, bio absorbable stent or a dual therapy stent or it can also be a covered stent.

- **Vascular Stents**

  Vascular stents are placed as a part of a peripheral stent angioplasty. Common sites which are treated with peripheral artery stents include carotid, femoral and iliac arteries. Because of the compressive and the mechanical forces which are applied at this point, the stents which are associated with these regions must be flexible.

  Materials like nitinol are used for these locations.

- **Ureteral Stents**

  Ureteral stents are used to open up and ensure the patency of a ureter which might be compromised. This is usually done as a temporary measure to prevent damage to a blocked kidney until the kidney stone which is causing the blockage can be removed.

- **Oesophageal Stents**

  Oesophageal stents are generally made of metal. Oesophageal stents are important tools for palliative treatment of inoperable oesophageal malignancies [6].Oesophageal stent is a flexible mesh and is about 2cm wide. These stents are used to allow the free movement of food from the oral cavity to the stomach via the oesophagus.

- **Biliary Stents**

  Biliary stents provide the drainage of bile juice from the bile ducts, pancreas and the gall bladder to the duodenum in conditions such as ascending cholangitis due to the obstruction of the passage way by the gall stones [7].It is usually made up of plastic or metal.

- **Prostatic Stents**

  These stents are placed from the bladder through the penile urethra and prostatic urethra to allow the drainage of a bladder through the penis. This is sometimes

required in benign prostatic hypertrophy. Prostatic stents are generally made up of plastic.

- **Duodenal Stents**

  An alternative to a stomach bypass operation is the insertion of a stent, which holds the sides of the duodenum open in the same way that a stent might relieve a blocked bile duct. The aim of putting in a stent is to allow food and other substances to pass through the stomach and reduce nausea and vomiting. Usually made up of metal or plastic.

Recent Advances in Stents

Glaucoma drainage stents have been very recently introduced and they are a very recent advancement which is still awaiting approval in several countries of the world. These stents are used to reduce the intraocular pressure in the eyes by providing a drainage channel for the fluid in the eye which gets collected during glaucoma. Some of the other types of stents are colon stents, duodenal stents and pancreatic stents. These stents are also a relatively recent development in the field of stents. Different types of stents are constantly being developed.

Drug Eluting Stents

A drug eluting stent is a metal or a ceramic tube which is placed in a blocked artery to block cell proliferation by slowly releasing drugs into the blood circulation. Drugs such as glucocorticoids (dexamethasone and betamethasone), heparin, hirudin, tocopherol, angiopeptin are some of the drugs that are delivered via stents. A drug-eluting stent which is also called DES is a peripheral scaffold which can also be placed in internal organs like the heart which is placed into narrowed and diseased peripheral or coronary arteries that work by slowly releasing a drug or several drugs to block the cell proliferation. Drug-eluting stents which are in current clinical use were approved by the Food And Drug Administration after several clinical trials showed that they were statistically and mechanically superior to baremetal stents for the treatment of coronary artery narrowing, and also having lower rates of major or also minor adverse cardiac events[8]. By the late 1990s, stents were used in almost

82 to 85% of percutaneous coronary interventions. Coronary interventions represent those that are done via a catheter and not by open chest surgery [9]. Early difficulties were also present with coronary stents which included a risk of early thrombosis which was resulting in the occlusion or blockage of the stent [10]. Coating stainless steel stents with other rare earth

metal substances such as platinum or gold did not eliminate this problem of early thrombosis whatsoever. High-pressure balloon expansion of the stent to ensure its full apposition and approximation to the walls of the arteries, combined with drug therapy using aspirin and another inhibitors of platelet aggregation almost completely eliminated the risk of early stent thrombosis. Though it occurred less frequently than with balloon angioplasty or other techniques, stents still remained highly vulnerable to restenosis, caused almost exclusively by the neo-intimal tissue growth. To overcome and prevent this issue of restenosis and occlusion, developers of drug-eluting stents used the devices themselves as a tool for delivering medication directly into the arterial wall or walls. While initial efforts were not very successful, the release of drugs with certain specific physicochemical properties from the stent was shown in the early 2000s to achieve high concentrations of the drug locally and directly at the target lesion, with minimal to nil systemic side effects. As currently used in clinical practice, "drug-eluting" stents refers to the metal stents that elute or deliver a drug or several drugs that are designed to limit the growth of neo-intimal scar tissue or tissue[s], thus reducing the likelihood of stent restenosis greatly. The first successful trials were of sirolimus-eluting stents were done in the early 2000s.

A clinical trial in the early 2000s led to an approval of the sirolimus eluting or releasing Cypher stent in Europe in 2002 by the Food and Drug Administration. After a larger pivotal trial that was published in 2003, the device received FDA approval and was released in the United States of America in 2003.Soon after their initial release, a series of trials of paclitaxel-eluting stents led to Food And Drug Administration approval of the Taxus stents in early 2004.The first stents that were classified or grouped as resorbable stent that was tested in humans was developed by the Igaki Medical Planning Company in Japan and was constructed from a form of polylactic acid. They published their early results in 2000. The German company named Biotronik later developed a magnesium absorbable stent and published their clinical results in 2007.The first company to bring a bio-resorbable stent to market was a company that goes by the name of Abbott Vascular which received a European marketing approval in September of 2012; the second was Elixir which received its Clinical excellence mark in May 2013

Dexamethasone releasing stents is one of the first ever generations of drug eluting stents that were used for local drug delivery to prevent or to address the issue of restenosis. Other glucocorticoids including betamethasone are also delivered via drug releasing stents to address restenosis. Drug eluting stents were first developed in an attempt to prevent or

address the issue of restenosis. Restenosis is the closure of a peripheral or coronary artery following a trauma to that artery or surrounding the areas supplied by the artery [12]. The basic mechanism of drug delivery from several of the drug eluting scaffolds involves encapsulating or coating a drug in a polymer or a combination of different polymers that can either allow the drug to diffuse outward from it or that it undergoes degradation in order to release the drug directly into the desired site. Polymers can also be subdivided into bioerodable or non-bio-erodable categories. The bio-erodable polymers can be further subdivided into two categories that are either bulk or surface erosion [13]. For long term effects, the non-bio-erodable stents are the most commonly used stents for this purpose. There are various drugs that are delivered through stents and these drugs can also be used to prevent restenosis. These drugs fall under four major categories [14].They are antineoplastics, immunosuppressive, migration inhibitors and also enhanced healing factors [15]. Anti-neoplastic drugs like Sirolimus that is currently undergoing research as CYPHER, tacrolimus, everolimus, leflunomide, M-prednisolone, cyclosporin are all some of the examples of the anti-neoplastic drugs that are delivered through stents[16].

Anti-proliferative compounds or preparations include drugs like paclitaxel, QP-2, actinomycin, statins and many other drugs. Paclitaxel was originally used to inhibit the tumour growth by assembling or aggregating microtubules that have been found to prevent cells from multiplying. It has also recently been noted that they can attenuate neo-intimal growth [17].

Immunosupressives: Taxol, actinomycin, methotrexate, angiopeptin are delivered through stents [18]. Immunosupressive drugs are generally drugs that are used to prevent the immune rejection of allogenic organ transplants. The general mechanism of action of most of these drugs is to stop cell cycle progression, by inhibiting the DNA synthesis of these cells. Everolimus, sirolimus, tacrolimus, ABT-578, interferon, dexamethasone, and cyclosporine are all examples of drugs working on such mechanisms of action. The sirolimus derived compounds appear highly reasonable in their ability to bring down and eliminate the neointimal thickening or thickenings [19].

Migration inhibitors: Batimistat, probucol are examples of migration inhibitors [20].These compounds are aimed at preventing endothelial cell migration to the inside of the stent. Once the smooth muscle cells migrate to the other side that is, the luminal side of the stent or stents in question, they can produce extracellular matrices and can start to occlude the blood flow greatly. Therefore by inhibiting their migration, they can have great therapeutic or medicinal applications for prevention of stent restenosis. Examples of these compounds are batimastat

and halofuginone. Batimastat, for example, is a potent inhibitor of matrix metalloproteinase enzymes. It can prevent the matrix degradation that is necessary for cells to free themselves to move. If the cells cannot move, they cannot invade the stent area [20].

Enhanced Healing Factors: VEGF is an example of an enhanced healing factor [21].Vascular endothelial growth factor (VEGF) promotes healing of the vasculature. In the context of stents, this would heal the implantation site and reduce platelet sequestration due to injury related chemotaxis. Nitrous oxide donor compounds may also replicate this effect. Healing of the vessel wall seems to be the gentlest approach to preventing ISR, but healing factors are still in the early stages of development for this application [22].The release of the drugs from the stents is principally based upon the process of diffusion [23]. Most of the drug eluting stents will operate through the principle of diffusion with the exception of a few stents undergoing clinical trials like CYPHER and TAXUS. The Cypher drug eluting stent manufactured by Cordis, a Johnson and Johnson company, utilized the drug Sirolimus to combat restenosis. The Cypher stent comes in a variety of lengths and diameters. These range from 8 to 33 mm in length and 2.5 to 3.5 mm in diameter. These coronary stents are constructed out of 316L stainless steel (low-magnetic, low-carbon) and are coated with a mixture of two polymers, parylene C, and the Sirolimus drug. The two non-erodible polymers (polyethylene-co-vinyl acetate (PEVA) and poly n-butyl methacrylate (PBMA)) are combined in a 67/33 percent ratio respectively and then applied to a parylene C coated stent. A drug free coat of PBMA is also applied to the stent surface to control drug release [24]. RAVEL and SIRIUS were two clinical trials which were conducted to test the efficacy of the CYPHER system [25]. Following up on the success of the Sirolimus-eluting Cypher stent manufactured by Cordis, Scientific designed their own drug-eluting stent in hopes of creating some competition in the drug-eluting stent in hope of taking some of Cordis's monopoly. The Boston Scientific stent, called Taxus, utilizes the drug Paclitaxel. Paclitaxel is in a class of drugs called taxanes. Its main uses are to prevent the growth of cancer cells in the body, treat metastatic breast cancer, metastatic ovarian cancer, and Kaposi's Sarcoma [26]. Paclitaxel works by promoting the assembly of microtubules and stabilizes them by preventing depolymerization. This stability results in an inhibition of the reorganization of the microtubule network during the cell mitotic process – thus preventing the accumulation of anti-inflammatory cells at the site of the injury. The Taxus stent comes in lengths of eight to 28 mm and diameters of 2.5 to 3.75mm. The stent is constructed out of 316L stainless steel and is coated with the Translute polymer [poly(styrene-b-isobutylene-b-styrene)]. This polymer functions similarly to the PEVA/PBMA copolymer used in the CYPHER stent. This

polymer is also notable for its excellent vascular compatibility, which is extremely important in a system designed for long-term implementation. The pharmacokinetics of the paclitaxel release are slightly different from the CYPHER stent: Burst release in the first 48 hours [27]. Paclitaxel and CYPHER stents are polymer based stents. Metallic stents are deployed in over 1.5 million patients in a year. Polymer-based coronary stents eluting sirolimus or paclitaxel substantially reduce the need for repeat percutaneous intervention compared with bare-metal stents, and drug-eluting stents are rapidly replacing bare-metal stents. [28]. Stent thrombosis is quite common in drug eluting stents. Stent thrombosis usually results in ST-segment elevation myocardial infarction or death. Angio- graphically documented late, greater than 6 months stent thrombosis is extremely rare with bare-metal stents except after intracoronary irradiation, which can delay the vascular healing.

Conclusion

A stent is still a foreign substance that has been introduced into the body, and the body will respond to the presence of the stent in a variety of ways. Macrophagesaccumulate around the stent and there is proliferation of the smooth muscle cells nearby. These changes, can lead to restenosis, and they are limited by the drugs that can be released by the stent, but these drugs will also limit formation of an endothelial layer over the new stent that has been introduced into the body to inhibit the formation of a blood clot. Endothelialization is an important feature of the vascular healing and is very important for the prevention of the thrombus formation. Lack of healing caused by certain drugs can also make the newly inserted stent an exposed surface on to which a clot, sometimes life-threatening, can be formed. For drugeluting stents, the presence of a clot formation within the stent may persist longer than usual when compared to others. It can maybe also last for as long as five years after the treatment has ended. Drug-eluting stents have been associated with a highly delayed arterial healing process. There is also evidence that drug-eluting stents might also be susceptible to thrombosis related to delayed endothelialisation of stent struts. Most probably, late thrombosis. [29]. Studies based on animals have also raised concerns regarding the fact that late thrombosis is very common among drug delivery through drug eluting stents but this can vary among humans and evidence so far, hasn’t been suggested. Evidence from animal models suggests that the Cypher sirolimus- eluting stent does not impede endothelialisation [30]. Despite overall improvements were made in the field of antiplatelet therapy, thrombotic events remain to be a very important cause of death after a percutaneous coronary intervention surgery. Sirolimus-releasing or delivering stents and the paclitaxel releasing or

delivering stents that are a polymer based group of stents have been proven to reduce neointimal hyperplasia and also other risks of restenosis while decreasing the risk of stent thrombosis by many folds.[31] Operators are now using drug-eluting stents as the primary choice of drug delivery for a wide variety of clinical and also for a wide variety of anatomic situations, many of which have not been evaluated in several of the randomized studies that have been published.

Abstract

Orthodontic treatment is based on the premise that when force is delivered to a tooth and thereby transmitted to the adjacent investing tissues, certain mechanical, chemical, and cellular events take place within these tissues, which allow for structural alterations and contribute to the movement of that tooth. Molecules present in drugs and nutrients consumed regularly by patients can reach the mechanically stressed paradental tissues through the circulation and interact with local target cells. The combined effect of mechanical forces and one or more of these agents may be inhibitory, additive, or synergistic. Current orthodontic research aims to develop methods of increasing the tissue concentration of molecules promoting tooth movement, while simultaneously decreasing the concentration of unwanted elements which can produce harmful side effects.The purpose of this review is to summarize the effects of some commonly used drugs on tissue remodeling and orthodontic tooth movement. A thorough knowledge about the drugs is therefore mandatory for the orthodontist dealing with patients under orthodontic treatment.

Key Words: Hormones, immunomodulatory drugs, immunosuppressant drugs, NSAIDs, orthodontic tooth

Introduction

Tooth movement is the key principle behind any orthodontic treatment. Orthodontic tooth movement is mainly a biological response towards mechanical force. It is induced by the prolonged application of controlled mechanical force on the tooth[1]. Molecules present in drugs and nutrients consumed regularly by patients can reach the mechanically stressed paradental tissues through the circulation and interact with local target cells. The combined effect of mechanical forces and one or more of these agents may be inhibitory, additive, or synergistic.[2] It is induced by the prolonged application of controlled mechanical force on the tooth, which eventually causes remodeling of the tooth socket by creating pressure and tension zones in the alveolar bone and periodontal ligament[1-2]. Strains of periodontal cells, bone-related cells, and extracellular matrix play a key role in orthodontic tooth movement (OTM)[3]. This strain forms changes in gene expression in the cells by interactions between the cells and the extracellular matrix, whereby integrins play an important role[4]. Various cell-signaling pathways are activated, ultimately leading to stimulation of periodontal ligament metabolism, and localized bone resorption and bone deposition.These interactions are regulated by local factors such as cytokines (IL-1), and growth factors, as well as by systemic factors such as parathyroid hormone, vitamin D, estrogen, or caicitonin

Rate of orthodontic tooth movementdepends on the amount of force applied, type of force appliedand the presence or absence of biologic modifiers thataffect bone metabolism. Different pharmacological agents aretried as biologic modifiers to alter the rate of orthodontic tooth movement. These interactions are regulated by local factors such as cytokines (IL-1), and growth factors, as well as by systemic factors such as parathyroid hormone, vitamin D, estrogen, or caicitonin. Drugs that alter or interfere with the inflammatory process will therefore have an effect on the tooth movement. Any pharmacologic agent or supplement consumed by a patient can reach the periodontal tissues through circulation and thus interacts with and influence a cell's response to orthodontic forces.[5]. These drugs may have dual effect on orthodontic tooth movement. They may either potentiate or inhibit tooth movement as well as exacerbate or reduce tooth resorptionThese drugs can be classified as drugs that potentiate or increase tooth movement

and drugs that inhibit or decrease tooth movement. As a clinician, this information is very important because orthodontic treatment does involve postoperative pain and the form of pain management is very important because not all drugs favours tooth movement. Many patients use over the counter medications for immediate pain relief, which may interfere with the treatment plan. Therefore, practitioners should have a proper knowledge of the drugs being prescribed and the patient should be well informed. In this study it is discussed about the effect of short and long term administration of medication on orthodontic tooth movement.[6]

Methods of Accelerating Tooth Movement

There are three phases of tooth movement: the initialphase, which is characterized by rapid movement afterthe application of force; followed by a lag period, wherelittle or no movement, and the last phase, where gradualor sudden increase of movement occurs.The early phase of tooth movement involves acute inflammatoryresponses characterized by leucocytes migratingout of blood capillaries and producing cytokines,which stimulates the excretion of prostaglandins andgrowth factors . The acute phase is followed by the chronic phase that involves the proliferation of fibroblast,endothelial cells, osteoblasts, and alveolar bonemarrow cells remodeling process.[7]

Drugs Affecting Tooth Movement

According to WHO (1966), drug is any substance or product that is used to modify or explore physiological systems or pathological states for the benefit of the recipient. During orthodontic treatment, drugs are prescribed to manage pain from force application to biological tissues, manage temporomandibular joint (TMJ) problems and tackle some infectionthroughout the course of treatment. Some of the drugs that have effect are on orthodontic tooth movement are Bisphosnates,Vitamin D,Fluoride,NSAID,Immunosuppressant Drugs,Anticancer Drugs And Hormones Like Estrogen Thyroid,Prostaglandin,Echistatin And RGD Peptide,Parathyroid,Corticosteroids.[8]

Bisphosphonates

Bisphosphonates (BPNs) have strong chemical affinity to the solid-phase surface of calcium phosphate; this causes inhibition of hydroxyapatite aggregation, dissolution, and crystal formationBisphosphonates are synthetic class of pyrophosphate analogues and they are powerful inhibitors of bone resorption.They act by inhibiting the osteoclastic activity and decreasing the number of osteoclasts.This leads to inhibition of orthodontic tooth movement and hence delays orthodontic treatment.The Topical application of bisphosphateis known to be very useful in anchoring and retaining teeth under orthodontic treatment. Bisphosphonates cause a rise in intracellular calcium levels in osteoclastic-like cell line, reduction of osteoclastic activity, prevention of osteoclastic development from hematopoietic precursors and production of an osteoclast inhibitory factor.[9]

Vitamin D3

Vitamin D3 is an important regulator of calcium homeostasis. 1,25 dihydroxycholecalciferol (1,25[OH]2D3) is the active metabolite of vitamin D3. Together with parathyroid harmones and calcitonin help in regulating the calcium and phosphate serum levels in the body. It also promotes the calcium and phosphate absorption in the intestine and reabsorption in the kidneys. Recent studies have proven that Vitamin D3 is very effective in treating osteoporosis and this explains how Vitamin D3 is considered as an active suppressor drug. It has been proven that it increases the bone mass, thus reduces fractures in osteoporotic patients[10].But some authors consider vitamin D3 to be a resorption promoting agent because it has stimulatory effects on osteoclasts23. Collins in 1988[11], demonstrated that local application of vitamin D3 improves the rate of tooth movement in rats. This result was due to the well-balanced bone turnover induced by vitamin D3. So more studies have to be conducted in determining the exact role of Vitamin D3 in orthodontic tooth movement.

Fluoride

Fluoride is one of the trace elements having an effect on tissue metabolism. Fluoride increases bone mass and mineral density, and because of these skeletal actions, it has been used in the treatment of metabolic bone disease, osteoporosis.active caries treatment by application of

sodium fluoride during treatment course may delay orthodontic tooth movement and increase the time of orthodontic treatment Sodium fluoride has been shown to inhibit the osteoclastic activity and reduce the number of active osteoclasts.[12]

NSAID

Most commonly used medications in orthodontics are for control of pain following mechanical force application to tooth. Nonsteroidal Anti-Inflammatory Drugs or generally called as NSAIDS is a very common drug in pain control.They have analgesic, antipyretic, and anti-inflammatory effects, and are prescribed for many conditions, such as rheumatoid arthritis, osteoarthritis, gout, dysmenorrhea, headache, migraine, and postoperative pain, as well as for the prevention of cardiovascular diseases and colorectal cancer. In cases of pain and headache, NSAIDs are taken incidentally because it is freely available over the counter.[13]

Acetylsalicylic acid and the related compounds, and their action result from inhibition of COX activity, which converts unsaturated fatty acids in the cell membrane to PGs Clinical experience shows that orthodontic tooth movement is very slow in patients undergoing long-term acetylsalicylic therapy.

Salicylate therapy decreases bone resorption by inhibition of PGs' synthesis and may effect differentiation of osteoclasts from their precursors. Therefore, it is recommended that patients undergoing orthodontic treatment should not be advised to take aspirin and related compounds for longer period during orthodontic treatment.[14]

Paracetamol has become one of the most popular antipyretic and analgesic drugs worldwide, and it is often also used in combination with other drugs which is a weak COX-1 and COX-2 inhibitor. The difference between NSAIDs and paracetamol is, NSAIDs acts by blocking COX-1 and COX-2, whereas paracetamol acts on a third isoform, COX-3 , which is expressed only in the brain and the spinal cord. As a result, paracetamol has minimal effects on prostaglandin synthesis In 1997, Roche JJ et al. reported that acetaminophen showed no effect on tooth

movement when tested on rats. paracetamoldoes'nt affect the orthodontic tooth movement, so it's safe to use as a choice of pain management in orthodontic treatment.[15]

Immunosuppressant Drugs

Patients with chronic renal failure or kidney transplants and on immunosuppressant drugs can encounter some difficulty during orthodontic treatment. Drug consumed for prevention of graft rejection (cyclosporine A) produce severe gingival hyperplasia, making orthodontic treatment and maintenance of oral hygiene difficult. Treatment should be started or resumed after surgical removal of excessive gingival tissues once there is good oral hygiene. Whenever possible, fixed appliances should be kept to a minimum period with brackets and avoiding the use of cemented bands. Removable appliances in these cases are not recommended due to improper fit.[16]

Anticancer Drugs

These are used for the treatment of childhood cancers. There is every chance of observing disturbances in dental as well as general body growth and development due to the adverse effects of the chemotherapeutic agents.Patients who had undergone chemotherapy with busulfan/cyclophosphamide belong to the risk group for orthodontic treatment.These drugs are known to produce damage to precursor cells involved in bone remodeling process, thereby complicating tooth movement.[17]

Phenytoin

Phenytoin results in gingival hyperplasia due to increased amountof gingival collagen fibers, which involve the interdental papilla, making application of orthodontic mechanics and maintaining oral hygiene difficult. If used during pregnancy, it can produce fetalhydantoin syndrome characterized by hypoplastic phalanges, cleft palate, hare lip, and microcephaly.[18] Valproic acid has a potential to induce gingival bleeding even with minor trauma, making orthodontic maneuvers difficult. Gabapentin of phenytoin group produces xerostomia, making oral hygiene maintenance difficult during orthodontic treatment.

Alcohol Abuse

Alcohol crosses the placental barrier and can stunt fetal growth or weight, create distinctive facial stigmata, damage neurons and brain structures, which can result in psychological or behavioral problems, and cause other physical damage (Fetal Alcohol Syndrome or FAS). The three FAS facial features are a smooth philtrum, thin vermilion, and small palpebral fissures. Chronic ingestion of large amounts on a daily basis may have devastating effects on a number of tissue systems, including skeletal system. Circulating ethanol inhibits the hydroxylation of vitamin D3 in liver, thus impending calcium homeostasis. In such cases, the synthesis of PTH is increased, tipping the balance of cellular function toward the enhanced resorption of mineralized tissues, including root resorption, in order to maintain normal levels of calcium in blood.[19] Davidovitch . have found that chronic alcoholics receiving orthodontic treatment are at high risk of developing severe root resorption during the course of orthodontic treatment.[20]

Hormones

Prostaglandins

The Prostaglandins are a chemical messengers called eicosanoids. It acts by regulating the synthesis of cyclic AMP in many tissues. Cyclic AMP is responsible in controlling the action of various hormones. This allows prostaglandin to affect a wide range of cellular and tissue functions. Prostaglandins are responsible in stimulating contraction of the smooth muscles of the uterus, affects blood flow, sleepcycle and also response to hormones such as adrenaline and glucagon. It also plays a role in elevating body temperature, which leads to inflammation and pain. According to Klein and Dowsett, prostaglandins play an significant role in promoting bone resorption. It is believed that, prostaglandins promote resorption by stimulating cells to produce cyclic AMP, which is a very important chemical messenger for bone resorption. In 1973, Goldhaber, reported that there is an increase in level of prostaglandins in periodontal diseases. In Orthodontics, Yamasaki and his teamswere the first to introduce the use of prostaglandins in controlling the rate of tooth movement. Results have showed that the local administration of PGE1 or PGE2 in the gingiva near the distal area of canines to be retracted, caused double the rate of tooth movement compared to the opposite, control side. . Studies on humans were

conducted in 1984, where Yamasaki studied the effects of PGE1 administration on orthodontic tooth movement. In the result the amount of tooth movement was twice compared to control sides. Lee[22] in a later study, compared lidocaine and PGE 1and reported that PGE 1 was more effective in bone resorption but it had certain side effects such as local irritation and phlebitis. Investigation in humans by Spielmann in 1989 with a split-mouth design showed significant increases in the rate of palatal premolar movement after multiple local injections of PGE1 at a dosage of 10 g. In india, Bhalajhi and Shetty conducted a study on the effect of exogenous administration of PGE2 in young rabbits. At the end there was a major increase in the amount of tooth movement clinically, and microscopically there were increase in the number of osteoclasts and resorption of lacunae. But there was a frequent need of administration of the drug as PGE2 gets metabolised rapidly in the lungs.

Estrogen

Estrogens do not appear to have any anabolic effects on bone tissue but there are studies indicating that estrogen directly stimulate the bone-forming activity of osteoblasts.They act by inhibiting interleukin-1(IL-1), tumour necrosis factor-a (TNF-a), and interleukin 6 (IL-6} which appears to be involved in bone resorption by stimulating osteoclastic activity.Oral contraceptive pills contains estrogen, when taken by younger woman for a long span, it can influence the rate of tooth movement.Therefore, it is extremely important for the dentist to consider this factor during history taking and treatment planning in females.[23]

Leukotrienes

Leukotrienes are a type of eicosanoid which is a product of arachidonic acid conversion and are the only eicosanoids that are formed independently from cyclooxygenase (COX). They are produced when arachidonic acid is metabolised by lipoxygenase enzymes[24].Leukotrienes also play an important role in Inflammation, allergies, and diseases such as asthma. These conditions can be cured by using leukotriene inhibitors which block leukotriene receptors hence counteracts their effects. Examples of medication are montelukast and zafirlukast. According to Mohammed AH 1989, leukotrienes causes

increase in orthodontic tooth movement, through bone remodeling whereas, leukotrine inhibitors work the other way round.Therefore, the use of leukotriene inhibitors can delay orthodontic treatment, leukotrienes can be used in future clinical applications that could result in increasing tooth movement.

Parathyroid Hormones

The function of parathyroid is to maintain a normal level of diffuse calcium and phosphorus in the blood plasma and to keep constant the ratio of these minerals to each other. The act as a check on the thyroid gland parathyroids are important organs in ca metabolism and play a leading role in calcification of teeth.After the complete development of tooth, there is no evidence of clinical case found with calcium withdrawal from teeth due to parathyroid disturbances. The parathyroid's are important in regulating blood ca level, but have little or no direct effect on growth or tooth eruption. PTH affects osteoblasts' cellular metabolic activity, gene transcriptional activity, and multiple protease secretion. Its effects on osteoclasts occur through the production of RANK-L Receptor activator of nuclear factor kappa -B legend), a protein playing a crucial role in osteoclasts' formation and activity[25]. In 1970s, animal studies demonstrated the Parathyroid hormone affects both bone resorption and formation process PTH could induce an increase in bone turnover that would accelerate orthodontic tooth movement. These results indicate that orthodontists should take note of patients being treated with PTH.[26]

Corticosteroids

Evidence indicates that the main effect of corticosteroid on bone tissue is direct inhibition of osteoblastic function and thus decreases total bone formation. Decrease in bone formation is due to elevated PTH levels caused by inhibition of intestinal calcium absorption which is induced by corticosteroids. Corticosteroids provokes the level of tooth movement, and since new bone formation becomes tough in a Patients who undergone treatment , they reduce the stability of tooth movement and stability of orthodontic treatment in general.When they are used for longer periods of time, the main side effect is osteoporosis is greater, but tooth movement is less stable since little bone is present and there is no indication of bone formation. These drugs are used as anti inflammatory and immunosuppressive agent in treatment of a wide range of chronic medical

conditions.[27] A low dose(1mg/kg body weight)decreases orthodontic tooth movement by suppressing osteoclastic activity. At an higher dose(15mg/kg body weight)it provokes the bone resorption activity thus results in more rapid orthodontic tooth movement and subsequent relapse The main effect of corticosteroid on bone tissue is direct inhibition of osteoblastic function and thus the decrease of total bone formation.[28] Decrease in bone formation is due to elevated parathyroid hormone levels caused by inhibition of intestinal calcium absorption which are induced by corticosteroids. [29]

Echistatin and RGD peptides

Echistatin is a strong inhibitor of tooth resorption.Therapeutic administration of eicosanoids resulted in increased tooth movement, whereas their blocking led to a decrease.olce et al made the first attempt in this aspect and reported that ELVAX-40 (a non-biodegradable,non-inflammatory, sustained release polymer) could be used to deliver integrin inhibitors like echistatinand RGD peptide agents (known to perturb bone remodeling), to decrease tooth movement at a particular level.[30]Recent research has even demonstrated decrease in root resorption following orthodontic force application after administration of echistatin.[31]

Thyroid Hormone

Thyroid hormones are recommended for the treatment of hypothyroidism and used after thyroidectomy in substitutive theraphy. Thyroxin administration lead to increased bone remodeling, increased bone resorptive activity and reduced bone density.Administration of thyroxine will lead to increase in bone remodeling, increase in bone resorption activity and reduces bone density.[32] Thyroxin produces interleukin 1 (IL-IB),a type of cytokine which involves in bone formation through osteoclastic reaction.Studies on rat have been conducted to determine the relationship between exogenous thyroxine and tooth movement. Results show that there was a significant increase in orthodontic movement compared to the control[33].

The thyroid hormone increases the speed of orthodontic tooth movement in patients undergoing such medication. Low dosage and short-term thyroxine administration are reported to lower the frequency of “force-induced” root resorption[34]. Reduced osteoclastic activity can may be

compared to a change in bone remodeling process and a reinforcement of the protection of the cementum and dentin to “force-induced” osteoclastic resorption.[35]

Discussion

This systematic review of literature summarizes the effects of medications, such as anti-inflammatory and anti-asthmatic , antiarthritics, analgesics, corticosteroids, estrogens and other hormones, and calcium regulators in orthodontic tooth movement. As described by Krishnan V and Davidovitch Z these groups of drug has an effect on OTM. Some of these drugs are promoter drugs where it promotes orthodontic tooth movement, but others have an inhibitory effect. Eicosanoids such as prostaglandins and leukotrienes are group of drugs, which increases the rate of OTM.They act by stimulating bone resorption. Eicosanoid inhibitors on the other hand acts in preventing OTM.[36] Example of eicosanoid inhibitors are NSAIDs where it inhibits the synthesis of prostanoids which is an important mediator of bone resorption. So, it is important that the patient does not take NSAIDs such as aspirin or other related compounds for long periods of time during orthodontic treatment[37]. The alternative that can be suggested to patients is paracetamols. Paracetamol also known as acetaminophen is a type of analgesic, which does not have any deleterious effect on OTM. Role of vitamin D3 and Corticosteroids in OTM still remains unclear. Some author have reported that it promotes tooth movement but there are also studies that demonstrate bone formation after application of these drugs. So, it is important to have more clinical trials on determining the exact role of Vitamin D3 and Corticosteroids in orthodontic tooth movement.[38] Bisphosphonates are drugs which also effect the calcium homeostasis. It is known for its role in inhibiting tooth movement. They are used in cases of prevention of orthodontic relapse but it should be used with great caution because of its severe side effects on long term use. Hormones also play an important role in tooth movement.[39] Hormones such as thyroxin is known to increase the rate of tooth movement by directly stimulating the action of osteoclast.Calcitonin and estrogen have the opposite effect on tooth movement. It is very important to know if the patient is under any oral contraceptive pills. It containsestrogens, which inhibits tooth movement.[40]

Conclusion

This review of literature summarizes the effects of medications, such as, analgesics, corticosteroids, estrogens and other hormones, and calcium regulators in orthodontic tooth movement. Some of these drugs are promoter drugs where it promotes orthodontic tooth movement, but others have an inhibitory effect. Hormones also play an important role in tooth movement. Hormones such as thyroxin is known to increase the rate of tooth movement by directly stimulating the action of osteoclast.Calcitonin and estrogen have the opposite effect on tooth movement. It is very important to know if the patient is under any oral contraceptive pills. It contains estrogens, which inhibits tooth movement.

Orthodontists have long observed that teeth move at different rates and individuals differ in their response to treatment. Some of the differences are caused by change in bone remodeling induced by drugs and systemic factors. All the drugs reviewed have the therapeutic effects as well as side effects that influence the cells targeted by orthodontic forces. The value of a thorough medical history is increasingly significant as young and old alike are exposed to a greater range of therapeutic agents. Therefore, it is imperative that the orthodontists need to pay attention to drug consumption and history of each and every patient, before and during the course of orthodontic treatment, so that the best treatment can be selected for each case.

Abstract

Drug metabolism is the biochemical modification of pharmaceutical substances or xenobiotics respectively by living organisms, usually through specialized enzymatic systems. Drug metabolism often converts lipophilic chemical compounds into more readily excreted hydrophilic products. Non steroidal anti inflammatory medicines(NSAIMs) are a class of drugs that provides analgesic and antipyretic effects, and, in higher doses, anti inflammatory effects. NSAIDs are metabolised primarily in the liver. They vary in half-lives and bio availability. They are classified as mild analgesics. NSAIDs inhibit the activity of both cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2), and thereby, the synthesis of prostagladins and thromboxane. NSAIDs are usually used for the treatment of acute or chronic conditions where pain and inflammation are present. The widespread use of NSAIDs has meant that the adverse effects of these drugs have become increasingly prevalent. NSAIDs, like all drugs, may interact with other medications.NSAIDs are mostly excreted as phase-II glucouronides and in a few cases as sulfate conjugates. Drug metabolism has an important role in the determination of the pharmacokinetic parameters like oral bioavailability, clearance and the half-life of the entity within the cell. The drug metabolic studies help to screen the compounds based on their metabolic rate. The various metabolic pathways of NSAIDs are reviewed.

Key Words:*Drugs, anti-inflammatory, metabolism, enzymes, liver*

Introduction

NSAIDs are non-steroidal anti-inflammatory drugs, also known as NAIDs, non-steroidal anti-inflammatory agents/analgesics (NSAIAs) or non-steroidal anti-inflammatory medicines (NSAIMs). They are medications with analgesic, antipyretic effects.In higher doses they also have anti-inflammatory effects - they reduce inflammation. Non-steroidal distinguishes NSAIDs from other drugs which contain steroids, which are also anti-inflammatory. NSAIDs are non-narcotic (they do not induce stupor). All NSAIDs are rapidly absorbed from the gastrointestinal tract, and thus almost all NSAIDs are available as oral preparations. NSAIDs are metabolised by the liver and excreted through urine. NSAIDs are usually used for the treatment of acute or chronic conditions wherepain and inflammation are present. The most prominent members of this group of drugs,aspirin, ibuprofen,diclofenac and naproxen are all available over the counter in most countries. Paracetamol (acetaminophen) is generally not considered an NSAID because it has only little anti-inflammatory activity. It treats pain mainly by blocking COX-2 mostly in the central nervous system, but not much in the rest of the body. This article reviews the metabolic pathways of various NSAIDs. It is generally accepted that non steroidal anti- inflammatory drugs (NSAIDs) act by inhibiting the synthesis of prostaglandins (PGs); however, this hypothesis may not account for all of the effects of NSAIDs at all dosages. For example, higher doses of NSAIDs are needed to suppress inflammation than are required to inhibit PG synthesis; moreover, sodium salicylate is an ineffective inhibitor of cyclooxygenase at concentrations used clinically. Alternative hypotheses have therefore been proposed in an attempt to explain fully the anti-inflammatory effects of NSAIDs, including their capacity at higher concentrations to blunt the functions of such inflammatory cells as the neutrophil. NSAIDs have also been found to disrupt a variety of processes at the plasmalemma that regulate the generation of twin signals. These effects, most likely due to the capacity of planar lipophilic NSAIDs to insert into the lipid bilayer, result in the disruption of signal transduction through the plasma membrane. Indeed, NSAIDs even inhibit activation of the primitive cells of marine sponges that neither respond to stable PGs nor contain a cyclooxygenase.

Whereas the inhibition of PG synthesis by NSAIDs is a satisfactory explanation for many of the pharmacologic actions and toxicities of NSAIDs, further studies are needed to clarify the entire spectrum of their anti-inflammatory activities.

Chronic pain remains a significant source of dis- tress and disability, particularly in the elderly population. It is estimated that 20% of individuals suffer from various forms of chronic pain worldwide [1]. Among this population, over 30 million people utilisenon-steroidal anti-inflammatory drugs (NSAIDs) for treat- ment of their discomfort. Approximately half of these patients are over the age of 65 years and use NSAIDs on a daily basis [2,3]. It is these patients that have the most comorbidity, which places them at highest risk of side effects. As the population ages, it is anticipated that the use of chronic pain medications for degenerative joint disease and other chronic ailments will only continue to increase. The most common pain medications used in these patients are NSAIDs as an alternative to opioid analgesics. Although initially viewed as a safer alternative in this particular population, emerging evidence suggests that the adverse effects on a variety of end organ systems may sometimes outweigh the analgesic benefits. Additionally, treatment costs of NSAID-induced cardiovascular (CV) and gastrointestinal (GI) side effects may negate the cost–effectiveness of oral administration of this class of medications when compared with topical preparations as measured by quality-adjusted life years [4].

Metabolism

The process by which the body brings about chemical changes in drug molecule is variously referred to as Drug metabolism or Bio transformation. Liver is the main organ involved in the process of bio-transformation. The enzymes involved in the biotransformation of drugs are distinct from those involved in carbohydrate, protein, and fat metabolism. These enzymes are called microsomal or nonmicrosomal. Microsomal enzymes are present in the smooth endoplasmic reticulum of the liver, kidneys, and gastrointestinal tract. Other enzymes are hydroxylase, dehydrogenase, reductase, glucuronly transferase, GSH-S-transferase, etc. Microsomal enzymes are responsible for glucuronide and some glutathione conjugations, most of the oxidation reactions, some reduction and hydrolysis reaction. These enzymes accept primarily the substrates of high lipid/ water partition coefficient. The activity of these enzymes can be stimulated (induced) or inhibited by prior or concomitant treatment with drugs. Nonmicrosomal enzymes are present in the cytoplasm, mitochondria and extracellular spaces of different organs. High concentrations are found in the liver, plasma, kidneys and other tissues. Other enzymes are esterase, amidase, hydrolase, sulfotransferase, GSH-S transferase, etc. They catalyze all conjugation reactions (except glucuronide and some of the glutathione conjugation), hydrolysis, and some oxidation and reduction reactions. The

substrate of high lipid/water partition coefficient. Most of these enzymes are not inducible a bit, they can be inhibited by drugs.[1]

Aspirin

Aspirin (acetylsalicylic acid) is a prodrug which is metabolically converted to salicyclic acid by the action of carboxylesterases. Aspirin is absorbed rapidly from the stomach and intestine by passive diffusion. Aspirin is transformed into active metabolite, salicylate in the stomach, in the intestinal mucosa, in the blood and mainly in the liver. Salicylate is the active metabolite responsible for most anti-inflammatory and analgesic effects. Therefore, aspirin has a very short half-life. Salicylate, in turn, is mainly metabolized by the liver. This metabolism occurs primarily by hepatic conjugation with glycin or glucuronic acid, each involving different metabolic pathways. The predominant pathway is the conjugation with glycin, which is saturable. With low doses of aspirin approximately 90% of salicylate is metabolized through this pathway. As the maximum capacity of this major pathway is reached, the other pathways with a lower clearance become more important. Therefore, the half-life of salicylate depends on the major metabolic pathway used at a given concentration and becomes longer with increasing dosage[2]. Salicylate is said to follow nonlinear kinetics at the upper limit of the dosing range.Urinary excretion of unchanged salicylate accounts for 10% of the total elimination of salicylate. Excretion of salicylate results of glomerular filtration, active proximal tubular secretion through the organic acid transporters and passive tubular reabsorption. Salicylate metabolites are also excreted in the urine.

Acetaminophen

Acetaminophen is a non-narcotic, analgesic and antipyretic drug, widely used as a pain relief medicine. APAP is rapidly absorbed from the gastrointestinal (GI) tract with peak concentrations achieved within 90 minutes of a therapeutic dose. The presence of food in the stomach may delay the peak but not the extent of absorption. Distribution is rapid with a volume of distribution (VD) of about 0.9 L/kg and minimal protein binding at thera- peutic concentrations. The half-life of APAP is 2.0 to 2.5 hours. Acetaminophen is metabolized in the liver by enzyme cytochrome P 450 to a highly reactive metabolite – N-acetyl-p-benzoquinoneimine (NAPQI), which can cause acute hepatic necrosis if not followed by conjugation with glutathione (GSH). The other known metabolic pathways of acetaminophen are via glucuronidation and sulfation. Metabolites separated include 2-methoxy-

acetaminophen, its glucuronide and sulfate conjugates, conjugated AAP, the sulfate conjugate of 2-hydroxyacetaminophen, glucuronide and sulfate conjugates of acetaminophen, S-(5-acetamido-2-hydroxyphenyl) cysteine, and S-(5-acetamido-2-glucuronosidophenyl)cysteine. Approximately 85% of a therapeutic dose undergoes phase II conjugation to sulfated and glucuronidated metabolites that are renally eliminated proportions of APAP are eliminated unchanged in the urine and by ring oxida tion to a catechol derivative.[3].

Indomethacin

Indomethacin is an anti-inflammatory antipyretic drug commonly used for symptomatic relief of pain and stiffness in rheumatic diseases.The drug has a biological half-life of about 5 to 10 hours and a plasma clearance of 1 to 2.5ml/kg/min. Indomethacin is distributed into the synovial fluid, is excreted in human breast milk and crosses the placenta in significant amounts. It is metabolised to O-desmethylindomethacin, N-deschlorobenzoylindomethacin and O-desmethy-N-deschlorobenzoylindomethacin, which are devoid of anti-inflammatory activity and are present in significant amount in the plasma. About 60% of an oral dose is excreted in the urine predominantly in glucuronidated form, while about 40% is excreted in the faeces after biliary secretion.[4]. A large amount of the dose undergoes biliary recycling. The biotransformation is independent of the route of administration. The drug has a biological half-life of about 5 to 10 hours and a plasma clearance of 1 to 2.5ml/kg/min.

Ketorolac

Ketorolac or ketorolac tromethamine is a non-steroidal anti-inflammatory drug (NSAID) in the family of heterocyclicacetic acidderivatives, used as an analgesic. Ketorolac acts by inhibiting the bodily synthesis of prostaglandins. Ketorolac tromethamine is largely metabolized in the liver. The metabolic products are hydroxylated and conjugated forms of the parent drug. The products of metabolism, and some unchanged drug, are excreted in the urine.[5].The principal route of elimination of ketorolac and its metabolites is renal. About 92% of a given dose is found in the urine, approximately 40% as metabolites and 60% as unchanged ketorolac. Approximately 6% of a dose is excreted in the faeces.

Mefenamic Acid

Mefenamic acid is a member of fenamate group of non-steroidal anti-inflammatory drug.

Mefenamic acid and its metabolites are firmly bound to plasma proteins. Mefenamic acid metabolism is predominantly mediated via cytochrome P450 CYP 2C9 in the liver. Two distinct metabolic products, one a hydroxymethyl derivative and the other a carboxy derivative, have been identified in both plasma and urine. Mefenamic acid and its two metabolic derivatives become conjugated with glucuronic acid through an ester linkage which is alkali labile and are excreted principally in the urine, but also to some extent in the bile and faeces.Following a single dose, 67% of the total dose is excreted in the urine as unchanged drug or as one of the two metabolites. 20% to 25% of the dose is excreted in the faeces during the first three days.[6].

Diclofenac

Diclofenac, a 2-arylacetic acid, nonsteroidal anti-inflammatory drug.The metabolism of diclofenac to its 5-hydroxylated derivative in humans is catalyzed by cytochrome P450.The biotransformation of diclofenac partly involves glucuronidation of the intact molecule, but mainly single and multiple hydroxylation followed by glucuronidation.About 60% of the administered dose is excreted in the urine in the form of metabolites from one of these two processes; less than 1% is excreted as unchanged substance. The remainder of the dose is eliminated as metabolites through the bile in the faeces.Diclofenac is completely absorbed from the enteric-coated tablets after their passage through the stomach. Following ingestion of one tablet with or after a meal, its passage through the stomach is slower than when it is taken before a meal, but the amount of active substance absorbed remains the same. In fasting subjects, the mean peak plasma concentration is attained on average 2 hours after ingestion of one 50 mg tablet. The plasma concentrations, as measured by the area under the time-concentration curve, are in linear relation to the size of the dose.Topical diclofenac is as effective as oral diclofenac in relieving joint stiffness and pain.[7]

Ibuprofen

Ibuprofen was developed by Boots (UK) in the 1950–1960's and after establishing its favourable safety profile at dose ranges for analgesic and anti-pyretic efficacy (up to 1200mg daily) it was the first NSAID (other than aspirin) to be approved for non-prescription (over-the-counter or OTC sale) use in the UK (in 1963), then the USA (in1964) and later in many other countries worldwide (Rainsford, 1999). Just after ibuprofen was developed, a large number of pharmaceutical companies undertook the discovery and development of NSAIDs

with a range of chemical and biological properties (Evans & Williamson, 1987; Otterness, 1995; Rainsford, 1999, 2004a; 2005a). Their anti-inflammatory, analgesic and anti- pyretic properties were discovered using animal models with some supportive properties being established in some biochemical systems which were known also to be important in inflammation (e.g. mitochondrial oxidative, intermediary and connective tissue collagen and proteoglycan metabolism; stability of albumin; and later oxyradicals).

Ibuprofen (IBU) is anon-steroidal anti-inflammatory drug (NSAID) widely used in the treatment of mild to moderate pain and inflammation.Ibuprofen is suitable for self medication with regards to its relatively wide spectrum of indication, good tolerance and safety.[8] This may be as a short term over-the-counter treatment for headaches, muscle aches or fever reduction or long-term, often prescription use, for arthritis and other chronic conditions. IBU inhibits the cyclooxygenase enzymes COX1 and COX2 coded for by PTGS1 and PTGS2, preventing the formation of various prostaglandins. The primary metabolism of IBU is oxidative and involves the cytochrome P450 enzymes. Ibuprofen is extensively bound to plasma proteins (99%) and extensively metabolised in the liver to two major inactive metabolites that are rapidly and completely excreted by the kidneys.[9].Like aspirin and indometacin, ibuprofen is a nonselective COX inhibitor, in that it inhibits two isoforms of cyclooxygenase, COX-1 and COX-2.However, the role of the individual COX isoforms in the analgesic, anti-inflammatory, and gastric damage effects of NSAIDs is uncertain and different compounds cause different degrees of analgesia and gastric damage.

Naproxen

Naproxen is a nonsteroidal anti-inflammatory drug. Administration of naproxen as the sodium salt (Anaprox), however, permits more rapid absorption from the gastrointestinal tract. In either form, the drug is essentially completely absorbed. Its metabolic half-life averages 13 hours. Naproxen is rapidly and completely absorbed from the gastrointestinal tract with an in vivo bioavailability of 95%. The rapidity, but not the extent, of absorption is influenced by the presence of food in the stomach. After administration of naproxen and naproxen sodium tablets, peak plasma levels are attained in 2 to 4 hours and 1 to 2 hours, respectively.[10] The metabolism of naproxen is quite simple: it is excreted almost entirely in the urine as the native molecule, its oxidative 6-desmethyl metabolite and their respective conjugates. Naproxen is an acidic drug that is highly bound to

plasma albumin. It may thus be expected to displace and transiently increase the tissue availability of other protein-bound drugs. In practice, however, potential interactions with both warfarin and tolbutamide have been evaluated and do not appear to be of clinical significance. Naproxen has a high therapeutic index and a shallow dose-response curve, so the effect of other drugs on its pharmacokinetics is not likely to have a large clinical impact.

Ketoprofen

Ketoprofen is a white or off-white, odorless, non-hygroscopic, fine to granular powder, melting at about 95°C. It is freely soluble in ethanol, chloroform, acetone, ether and soluble in benzene and strong alkali, but practically insoluble in water at 20°C. Ketoprofen is rapidly and well-absorbed, with peak plasma levels occurring within 0.5 to 2 hours.When Ketoprofen is administered with food, its total bioavailability (AUC) is not altered; however, the rate of absorption is slowed.The metabolic fate of Ketoprofen is glucuronide conjugation to form an unstable acyl-glucuronide. The glucuronic acid moiety can be converted back to the parent compound. Thus, the metabolite serves as a potential reservoir for parent drug, and this may be important in persons with renal insufficiency, whereby the conjugate may accumulate in the serum and undergo deconjugation back to the parent drug (see Special Populations, Renally Impaired). The conjugates are reported to appear only in trace amounts in plasma in healthy adults, but are higher in elderly subjects-presumably because of reduced renal clearance [11]. There are no known active metabolites of Ketoprofen. Ketoprofen has been shown not to induce drug-metabolizing enzymes.

Piroxicam

Piroxicam, an oxicam, is a non-steroidal anti-inflammatory drug (NSAID) which is structurally related to tenoxicam, another NSAID.The plasma half-life in humans is approximately 36 to 45 hours and stable plasma concentrations are maintained throughout the day on once daily dosage. Following repeated administration, plasma concentrations increase for five to seven days, by which time a steady state is reached which is not exceeded following further constant daily drug administration. Piroxicam is extensively metabolised, with less than 5% of the daily dose excreted unchanged in urine and faeces. One important metabolic pathway is hydroxylation of the pyridyl ring of the piroxicam side chain, followed by conjugation with glucuronic acid and urinary elimination. Approximately 5% of the dose is metabolised to and excreted as saccharin.[12]

Meloxicam

Meloxicam is a non-steroidal anti-inflammatory drug (NSAID). Meloxicam is eliminated almost entirely by hepatic metabolism: two thirds by cytochrome (CYP) P450 enzymes (CYP2C9 two thirds and CYP3A4 one third) and one third by other pathways, such as peroxidase oxidation. Meloxicam is almost completely metabolised to four pharmacologically inactive metabolites. The major metabolite, 5'-carboxymeloxicam (60% of dose), from CYP2C9 mediated metabolism, is formed by oxidation of an intermediate metabolite 5'-hydroxymethylmeloxicam, which is also excreted to a lesser extent (9% of dose). In vitro studies suggest that CYP2C9 plays an important role in this metabolic pathway, with a minor contribution from the CYP3A4 isoenzyme[13]. The patient's peroxidase activity is probably responsible for the other two metabolites which account for 16 and 4% of the administered dose respectively.

Celecoxib

Celecoxib is a nonsteroidal anti-inflammatory drug (NSAID) with anti-inflammatory, analgestic, antipyretic properties. It is approved for the treatment of osteoarthritis, rheumatoid arthritis, ankylosing spondylitis, and acute pain.After oral administration, celecoxib is rapidly absorbed and achieves peak serum concentration in about 3 hours. It is extensively metabolized in the liver with very little drug (<3%) being eliminated unchanged.The major routes of excretion for celecoxib are feces and urine. Celecoxib is metabolized primarily through methyl hydroxylation to form hydroxycelecoxib. This reaction is largely catalyzed by CYP2C9, although CYP3A4 also plays a minor (<25%) role. Hydroxycelecoxib is further oxidized to form carboxycelecoxib via cytosolic alcohol dehydrogenases ADH1 and ADH2, then conjugated with glucuronic acid via UDP glucuronosyltransferases (UGTs) to form the 1-O-glucuronide. None of the metabolites are pharmacologically active.Since celecoxib metabolism is predominantly mediated via CYP2C9, polymorphisms in CYP2C9 are likely to have a direct impact on celecoxib pharmacokinetics and variability in drug responses.[14]

Combination of Paracetamol and Ibuprofen

There are an increasing number of products being marketed to the public that contain both paracetamol and ibuprofen. It is uncertain whether the concomitant use of paracetamol and ibuprofen significantly improves analgesia compared to the use of NSAIDs alone. Studies

have produced mixed results and outcomes may be influenced by the cause of the pain being studied. It is also not clear whether the combined use of paracetamol and ibuprofen increases the risk of adverse effects.(15)

A Cochrane review of the analgesic efficacy of paracetamol and ibuprofen in the treatment of post-operative pain, concluded that combinations of paracetamol plus ibuprofen provided better analgesia than either medicine alone.(16) It was also concluded that the combination treatment reduced the need for additional analgesia to be administered and reduced the risk of adverse events occurring.A study of approximately 900 patients using paracetamol or ibuprofen, or a combination of the two, for the treatment of osteoarthritis of the knee found significantly more patients achieved pain control at ten days and at 13 weeks with the combination treatment compared to paracetamol alone, but there was not a statistically significant difference compared to using ibuprofen alone.(17) In contrast, a small study of 90 patients randomised to one of three treatment groups in an emergency department setting found that combination treatment with paracetamol and ibuprofen did not provide more effective pain relief following musculoskeletal injury compared to either medicine alone.

A large British study funded by a pharmaceutical company reported that compared to the use of the paracetamol and ibuprofen alone, the combined use of the two medicines did not increase the number of adverse effects. However, in the treatment of osteoarthritis of the knee a trend towards increased dyspepsia, diarrhoea and blood loss was reported in patients using a combination product.(18)

The lack of a demonstrated strong synergistic analgesic effect between paracetamol and ibuprofen, suggests that the two medicines may have similar modes of actions and their effect may not be additive. The lack of clear evidence of improved analgesia has led some experts to question the value of combination products containing paracetamol and ibuprofen.

The combination of paracetamol with NSAIDs may provide more effective analgesia for some patients, e.g. for post- surgical pain, than either medicine alone. This combination treatment may allow the dose of NSAID required to achieve analgesia to be reduced (compared to NSAID treatment alone) therefore reducing the amount NSAID-related risk the patientis exposed to. However, this approach does not appear to be effective for all conditions. If a combination of paracetamol and NSAIDs is used to treat pain, consider titrating the NSAID dose downwards as pain becomes more manageable, while continuing treatment with paracetamol at the same dose. The NSAID can then be withdrawn, before

paracetamol, and treatment with paracetamol continued, as required. If the risk of NSAID-related adverse events is high, it may be appropriate to consider adding codeine to paracetamol, in preference to NSAID treatment. For example, an older patient with osteoarthritis, diabetes and chronic kidney disease (CKD) may be particularly susceptible to the nephrotoxic effects of NSAIDs.(19).

An appropriate starting dose of codeine in combination with paracetamol for mild to moderate pain in adults is 15 mg, every four hours, as required. Codeine can be given in doses up to 60 mg, if required, but the total dose should not exceed 240 mg per day. The main adverse effects of codeine are gastrointestinal disturbance and potential respiratory depression The effective of codeine may vary between individuals due to genetic differences in metabolism, and it may not be an appropriate choice for all patients.(20)

Conclusion

The non-steroidal antiinflammatory drugs (NSAIDs) are widely used for the treatment of pain and for the management of edema and tissue damage resulting from inflammatory joint disease (arthritis).Drug metabolism has an important role in the determination of the pharmacokinetic parameters like oral bioavailability, clearance and the half-life of the entity within the cell. The drug metabolic studies help to screen the compounds based on their metabolic rate. Drug metabolism is very essential in the toxicity studies too. The persistence of the compounds in the systemic circulation for long period causes toxicity and the nature of the metabolites and the reaction of the metabolites within the body, must be studied thoroughly before the compounds progress to the next stage of screening in drug discovery process. In this way, it is seen that drug metabolic studies form an integral part in drug discovery. Since NSAIDs are commonly used drug, it is important to know the metabolism of various NSAIDs and excretion for its proper use in particular disease condition .

Abstract

Dysmenorrhea is a common menstrual complaint with a major impact on women's quality of life, work productivity, and health-care utilization. The prevalence of dysmenorrhea varies between 16% and 91% in women of reproductive age, with severe pain in 2%–29% of the women studied. Women's age, parity, and use of oral contraceptives were inversely associated with dysmenorrhea, and high stress increased the risk of dysmenorrhea. Inconclusive evidence was found for modifiable factors such as cigarette smoking, diet, obesity, depression, and abuse. Dysmenorrhea is a significant symptom for a large proportion of women of reproductive age; however, severe pain limiting daily activities is less common.The main aim of this review article is to know in detail about Dysmenorrhea in Women.The objective of this article is to know about dysmenorrhea in women, what is the cause, what are the consequences and why is it happening and also to know about dysmenorrhea in all aspects and to know the opinions from different authors.

The present study was to know about Dysmenorrhea in women. Various articles from different authors were collected and summed up as a review article so that Dysmenorrhea in women is known elaborately in all aspects. In conclusion, this review shows that dysmenorrhea is a significant symptom for a large proportion of women throughout the reproductive years. Severe dysmenorrhea limiting daily activities is much less common. Improvement of the symptom over time has been observed, although many women also experience unchanged or worse symptoms. Dysmenorrhea is inversely related to age, parity or number of livebirths, and oral contraception use. Dysmenorrhea is positively associated with stress related to both work and general life, as well as with family history of dysmenorrhea.

Key Words: *Dysmenorrhea, women, menstruation, painful periods, abdomen.*

Introduction

Dysmenorrhea or painful menstruation is defined as a severe, painful, cramping sensation in the lower abdomen that is often accompanied by other symptoms, such as sweating, headaches, nausea, vomiting, diarrhea, and tremulousness, all occurring just before or during the menses [(1).] There are 2 types of dysmenorrhea: Primary dysmenorrhea refers to pain with no obvious pathological pelvic disease and almost always first occurs in women 20 years or younger after their ovulatory cycles become established [(1).] Secondary dysmenorrhea is caused by underlying pelvic conditions or pathology and is more common in women older than 20 years [(1, 2).]

Dysmenorrhea is considered the most common symptom of all menstrual complaints and poses a greater burden of disease than any other gynecological complaint in developing countries [(3).] Among women of reproductive age worldwide, dysmenorrhea is more prevalent than the other 2 common types of chronic pelvic pain, namely, dyspareunia and noncyclical chronic pelvic pain [(4).] Being a debilitating condition for many women, it has a major impact on health-related quality of life, work productivity, and health-care utilization [(5–9).] As a result, dysmenorrhea is responsible for considerable economic losses due to the costs of medications, medical care, and decreased productivity [(1).] The prevalence of dysmenorrhea reported in the literature varies substantially. A greater prevalence was generally observed in young women, with estimates ranging from 67% to 90% for those aged 17–24 years [(10, 11).]

A recent large Australian study of senior high school girls found that a higher proportion, 93%, of teenagers reported menstrual pain [(12).] The studies in adult women are less consistent in reporting prevalence of dysmenorrhea and often focus on a specific group, with rates varying from 15% to 75% [(10).] Severe pain sufficient to limit daily activities is considerably less common, affecting approximately 7%–15% of women [(10),] although a study of adolescents and young adults aged 26 years or less reported that 41% of the participants had limitations in their daily activities due to dysmenorrhea [(7).]

A range of risk factors for dysmenorrhea have been identified in the literature, although mixed results have been observed for many of these factors. In general, increased severity of dysmenorrhea has been suggested to relate to age [13–15], smoking [14, 16, 17], higher body mass index [18], earlier age at menarche [15, 18], nulliparity [15, 19], longer and heavier menstrual flow [15, 18], and family history of dysmenorrhea [20]. Women using oral contraceptives generally report less severe dysmenorrhea [14, 15, 21]. Depression and stress have also been shown to increase the risk of dysmenorrhea [9, 22]. Other common factors, such as education [23], marital status [14], employment [19], alcohol consumption [17, 18], and physical activity [15, 18], show largely negative or inconclusive results.

Materials and Methods

The present study was to know about Dysmenorrhea in detail. Various articles from different authors were collected and summed up as a review article so that dental crowding is known elaborately in all aspects. The articles were collected by manual searching of the references of the relevant retrieved articles, peer-reviewed physiologic journals, and gray literature. Search terms included dysmenorrhea, menstruation, women,painful periods. Non-English articles were excluded from the review in the study-selection stage. Data extraction and evaluation of primary studies were performed independently by 2 reviewers.

Discussion

Knowledge of physiology of reproduction is important for teenage girls to practice menstrual hygiene [47]. Dysmenorrhoea is a common distressing disorder in women that manifests during menstrual phase especially in young females [51]. Primary dysmenorrhea is a medical condition of pain which is worst during first day of menstruation that interferes with daily activities. It is not associated with any pathological changes.[48]. Dysmenorrhea is defined as painful menstrual cramps of uterine origin. It is the common gynecological condition that can affect as many as 50% of women[49].

Onset of menstruation, menarche is a part of many adolescence changes, is a very important emotional land mark for every girl. It may be associated with some menstrual problems like dysmenorrhea. This condition is commonly observed between the ages of 15 and 25

years.Dysmenorrhea is classified in to two types, Primary, which usually begins shortly after the onset of menstruation and secondary dysmenorrhea, which develops later in life and mostly is associated with pelvic abnormalities.

Its prevalence varies from 40% to 90% according to different studies. The exact etiology of dysmenorrhea is unknown but it is thought to be caused by release of prostaglandins, which causes uterine contractions and pain. In some studies it is mentioned that it results from hypoxia and ischemia even though vasopressin may also play a role in increasing uterine contractility, causing ischemic pain and elevated levels of vasopressin evaluated in women with primary dysmenorrhea. Where most of the females experience some degree of pain and discomfort in their menstruation but approximately 10-15% of the women have severe dysmenorrhea which significantly affects the quality of life and could have impacts on daily activities, social and academic performances at their workplace or at home.

Dysmenorrhea is found to be the leading cause of short term school absenteeism from 38 to 45.6% mentioned in different studies, 58.9% reported decreased daily activity & socialization 46%. Risk factors for dysmenorrhea include nuliparity, heavy menstrual flow, smoking and depression. There are certain risk factors which are seemed to be associated with more severe dysmenorrhea like earlier age at menarche, long menstrual periods, heavy menstrual flow, smoking and positive family history. Somehow women differ considerably in their individual risks of dysmenorrhea for reasons that are largely unknown.

Still limited data is available in this regard which can avert the relationship of positive family history in occurrence of dysmenorrhea and severity of condition. Therefore present study was carried out to evaluate familial predisposition of primary dysmenorrhea among the medical students with positive family history.

It has been estimated that 7–15% of women suffer from severe pain which causes disturbances in their performance for 1–3 days in a month, and 14–52% of female students miss school because of complaining dysmenorrhea. This issue is associated with decline in career and educational function and results in disturbed quality of life and emerging economic problems.

Various reasons have been proposed for primary dysmenorrhea such as progesterone reduction in the final stages of luteal phase that causes lissom rupture and subsequent release of A2 phospholipase of the endometrium. Origin of increasing phospholipase is prostaglandin that causes retraction of uterine muscles vessels which finally result in ischemia and pain. However, mild physical activities, proper diet, relaxation, massage, biofeedback techniques, some Yoga exercises, contraceptive pills, and nonsteroidal anti-inflammatory drugssuch as mefenamic acid and ibuprofen are recommended for decreasing the pain of primary dysmenorrhea.

Since most of the drugs utilized for controlling the pain of dysmenorrhea have various side-effects and also are expensive, most of the nonpharmacological methods are in the category of complementary medicine for this disorder. The use of nonpharmacological methods such as aromatherapy, massage, acupuncture, and acupressure are also having been popular in the recent years. Traditionally, aromatherapy has been used as one of the nonpharmacological methods for reducing the symptoms of dysmenorrhea, releasing uterine cramps, and decreasing the pain and anxiety after childbirth[22-25].

However, a common complementary drug which has been used in aromatherapy is lavender that belongs to the Mediterranean region and it is found in Africa and India. Lavender is just a little herbaceous plant with narrow and long leaves, covered by white cottony fluff and purple flowers and is in the form of a spike. Its essence is made from distilling flowers from blossoming plants, and its muscle relaxant and antispasmodic effects have been confirmed by many studies.

Some studies suggest lavender and its main extract such as linalool acetate and linalool had topical analgesic effects on laboratory animals, which is made by increasing regional perfusion. Results of studies supporting aromatherapy suggest that essential oils stimulate the receptors in the olfactory bulb and transfer the message of olfaction to limbic system and cause releasing endorphin, encephalin, and serotonin, which results in the sense of relaxation and stress reduction[26,28]

About the prevalence of the primary dysmenorrhea and the side effects of the current treatments and because of lack of similar studies in this field, we decided to perform a study on the female

students in dormitories of Ardabil University of Medical Sciences with the aim of determining the effect of lavender aromatherapy on the pain severity in primary dysmenorrhea.

Dysmenorrhea is one of the most common gynecological problems among female students, which may be the leading cause of absenteeism from college. Dysmenorrhea is of two types. The primary is a menstrual pain without any organic pathology. When the pelvic pain is associated with identifiable pathological conditions, it is called secondary. Dysmenorrhea also may be due to anxiety, emotional instability, a faulty outlook on sex and menstruation, or imitation of the mother's feelings about menstruation. Researchers reported that excessive production of prostaglandins, which causes severe uterine contractions, which cause pain and decrease blood flow and oxygen to the uterus. Similar to labour pains, these contractions can cause significant pain and discomfort. Prostaglandins may also contribute to nausea and diarrhoea[49].

Most studies show that dysmenorrhea is a common problem affecting the majority of women in the community. Severe pain or pain limiting women's daily activities, however, occurred only in 2%–28% of adult women. Self-medication is a worldwide problem and it is common in developing countries like India every day, everywhere, consumers reach for self-care products to help them through their common health problems.[50]

The lowest rate of 2% reported in a longitudinal study was possibly due to potential underreporting as 74% of the included women were employed and thus less likely to stay in bed and miss work, which is used to define severe pain in the study [37]. The prevalence of severe pain reported in this review appears to be higher than the 12%–14% reported in community-based studies in the World Health Organization review [4] but comparable with 5%–20% reported in another review of the condition in developing countries [38].

Weissman et al. [37] found that dysmenorrhea persisted over the 6-year follow-up among the majority of women reporting it at baseline, and improvement or worsening of the symptom was equally likely. In their multivariable analysis, the presence of dysmenorrhea at baseline (excluding women with severe dysmenorrhea) was a strong predictor of reporting moderate or severe dysmenorrhea at follow-up (odds ratio = 7.48, 95% CI: 3.09, 18.15). More studies are

needed to explore the natural history of the symptom. Despite some disagreement, the majority of the previous literature generally demonstrates an inverse association between both age and parity and dysmenorrhea

This association was confirmed by the vast majority of studies included in this review, consistent across different types of study, although 3 studies failed to adjust for parity in their analysis on the association between age and dysmenorrhea [30]. Interestingly, Burnett et al. [26] found that the effect of age remained in the adjusted model including nulliparity, whereas the association between nulliparity and primary dysmenorrhea was no longer significant when controlled for age and smoking ($\beta = 0.93$; $P = 0.582$). It is unclear though what the proportion of nulliparous women was in the study.

Furthermore, the study did find that the women most debilitated by pain were significantly more likely to be nulliparous. Nevertheless, the longitudinal study by Weissman et al. [37] provides stronger support for the inverse association between both age (odds ratio = 0.92, 95% CI: 0.86, 0.98) and livebirth (odds ratio = 0.20, 95% CI: 0.08, 0.53) and the severity of dysmenorrhea after controlling for each other; however, parity clearly had a much stronger effect in their analysis. In addition, the study also found that gravidity was less influential than livebirth, consistent with other studies showing no effect from pregnancies ending in miscarriage or abortion [15, 41].

Different mechanisms have been proposed for the relation between livebirth and dysmenorrhea. One is related to the pathogenesis of primary dysmenorrhea of the close association with elevated prostaglandin levels in the secretory endometrium that triggers pain. After a term delivery, the endometrium may release a lower level of prostaglandins, resulting in decreased pain [41]. Another hypothesis is that neuronal degeneration in the uterus following term pregnancy, due to disappearance of uterine adrenergic nerves and a decrease in uterine noradrenaline in the third trimester of pregnancy, may explain the disappearance or reduction of menstrual pain after childbirth [15].

A strong effect of family history of dysmenorrhea and risk of dysmenorrhea was shown in 2 studies, which is in line with some previous studies reporting a similar association, suggesting genetic susceptibility to dysmenorrhea among women with variant genotypes in a number of

metabolic gene polymorphisms [20, 43]. However, other possible explanations are that the association could be related to conditioned behavior that is learned from mother or sisters for the possibility of societal reward or that control for pain exists [25-28]. Alternatively, it could be simply due to similar living patterns and lifestyles in the families [34]. Among the range of lifestyle and other demographic factors studied such as smoking, body mass index, and socioeconomic status, conflicting results were shown.

Previous studies on the association between smoking and dysmenorrhea are mixed. Although most cross-sectional studies show an increased risk among smokers [13, 14, 16], a negative effect was also seen [44]. Inconsistent results have also been observed for smoking and the incidence or the severity of dysmenorrhea in longitudinal studies [15, 18].Sundell et al. [15] found that the prevalence and severity of dysmenorrhea were increased in smokers and that the severity increased with the number of cigarettes smoked per day.

On the other hand, Harlow and Park [18] found that smoking was not associated with the probability of having pain or severe cramps but, among those with pain, smokers were more likely to have pain lasting longer than 2 days. Similarly, being overweight was found to be an important risk factor for the probability of experiencing pain and for increasing duration of pain in 1 longitudinal study [18], and severity of dysmenorrhea was not associated with either height or weight in another [15].

The systematic review also failed to detect a significant association between obesity and dysmenorrhea in the pooled analysis of 5 studies [40]. No association was shown among women's education, marital status, alcohol use, and the risk of dysmenorrhea in the current review, which is supported by the recent systematic review identified [40] and previous studies.

Dysmenorrhea or painful menses is unfortunately a very common condition and one that some women often come to accept as a normal occurrence in their lives. However anything beyond very mild discomfort at the onset of the cycle is a sign some aspect of the cycle needs to be addressed and Chinese Medicine has many tools to assist in this area.

There is an old saying in Chinese which translates as "Where there is free flow there is no pain and where there is pain there is no free flow". Basically stating that wherever we have pain there

is something restricting the optimal flow of blood and nutrients into an area. Common causes include; excessive tension causing sluggish flow, lack of warmth which allows the buildup of cold in the tissues and subsequent contraction or can be due to blood deficiency where it is not adequately nourishing the involved tissues and organs of the body and leading to complications.

When symptoms are worse in the days leading up the cycle and improve after the flow starts in earnest this is due to an excessive amount of tension in the system; often due to chronic mental stress and irritation or can be due to a blockage in the downward descent of Blood through the channels linked to the uterus .

Treatment is targeted towards re-establishing healthy movement of Blood and throughout the body mainly by working on the relationship between the Liver or GallBladder and the Spleen meridians.

Another common contributing factor is the accumulation of cold in the tissues of the lower abdomen. This can be due to environmental factors which lead to direct exposure such as; leaving the mid rift exposed during cooler weather, swimming in cold water during the menses, sitting on cold floors or excessive intake of iced products.

This accumulation can also arise from internal reasons. This can be due to lifestyle factors or convalescence from an illness that has led to the gradual exhaustion of the bodies. This exhaustion then allows the body temperature to drop and blood to stagnate and the tissues to contract manifesting with pain and inhibited menstrual flow.

When discomfort increases towards the end of menstruation this shows an underlying deficient condition in the body that has been exacerbated by the further loss of blood. Treatment then aims to build up and strengthen the body focusing on the quality and volume of the blood and the underlying organ deficiencies or lifestyle patterns that have contributed to the development of the condition. Excessive mental activity, worry or anxiety, heavy exercise or work schedule, chronic illness or dietary imbalances may all contribute to this condition.

However, caution should apply when interpreting the systematic review results, as heterogeneity was present in all analyses with multiple studies, and the review is based largely on case-control studies that are subject to recall bias. A protective effect of OCPs or other forms of hormonal contraceptive for dysmenorrhea is evident in the majority of previous studies [10, 13–15, 21], consistent across different study types.

This is largely confirmed by the current review, although 1 of the studies on a large sample of Indian women did not show any significant association between different methods of contraception, including OCPs, and moderate to severe dysmenorrhea [3].

The reason for this discrepancy may be due to the small number of women using OCPs (n = 43) in the study. There is evidence suggesting an association between early age at menarche and increased risk of dysmenorrhea [15, 18, 19], which is supported by the systematic review [40]. However, most of the studies reporting it in this review failed to show an association [26, 31, 35] with the exception of the Indian study [3].

The reason for the discrepancy is not readily apparent, and the association may be confounded or mediated by other factors. Furthermore, although there is suggestion of some associations of other reproductive factors such as age at first birth, cesarean section, and heavy and irregular menses [14, 18, 41], this review is unable to reach any firm conclusion because of the limited number of studies reporting these effects. Among the psychological factors studied, a positive association between perceived stress, related to work or general life events, and the risk of dysmenorrhea was shown in most included studies.

The biological mechanism for association between work stress and dysmenorrhea is not well understood, although potentially through a cascade of neuroendocrine responses [36]. Stress inhibits the release of follicle-stimulating hormone and luteinizing hormone, leading to impaired follicular development. This can alter progesterone synthesis and release, which may influence the activity of prostaglandin.

Besides progesterone, stress-related hormones, including adrenaline and cortisol, also appear to influence prostaglandin synthesis and/or binding in the myometrium [36].

Furthermore, mental health may act as a mediator in the relationship between stress and dysmenorrhea, with high job stress increasing the risk of mental health morbidity, which in turn is positively related to painful menses [28]. Of note is that these studies were generally conducted on groups of employed women, whereas another included crosssectional study of a random sample of Iranian women did not observe a significant association between stress level and the severity of pain in the adjusted analysis [34].

Conclusion

In conclusion, this review shows that dysmenorrhea is a significant symptom for a large proportion of women throughout the reproductive years. Severe dysmenorrhea limiting daily activities is much less common. Improvement of the symptom over time has been observed, although many women also experience unchanged or worse symptoms. From longitudinal or population data, this review has confirmed the following:

• Dysmenorrhea is inversely related to age, parity or number of livebirths, and oral contraception use;

• Dysmenorrhea is positively associated with stress related to both work and general life, as well as with family history of dysmenorrhea.

However, uncertainty still remains for a number of lifestyle factors, such as smoking, obesity and diet, psychological factors, and environmental factors. Furthermore, there is a lack of longitudinal datato study the natural history of dysmenorrhea and the effects of a range of modifiable risk factors over time. More research on these from population-based, prospective, longitudinal studies to generate robust evidence will help to support targeted preventive interventions.

Abstract

People believe and trust that plant based medicines are natural and are effective with no or fewer side effects. However it may or may not be true for each and every plant, unless they are clearly studied and identified its uses. Still there are numerous numbers of plants whose medicinal purposes are unknown to us, and there still under research of its uses. Bacopamonnieri is a perennial herb. Bacopamonnieri is an Indian system of medicine; it is most commonly called brahmi. Bacopamonnieri was the most important medicinal plants, for their medicinal importance, commercial value and its potential for future researches [1]. This herb has been taken to sharpen intellect and attenuate mental deficits [2]. In Ayurvedic, B. monnieri has been used to promote memory and to treat psycho neurological disorders, treating insanity, epilepsy, hoarseness and as a rejuvenator. In the last four decades the plant and the compounds isolated from it, especially the saponins, have been studied extensively regarding their memory-enhancing activities and their ability to improve cognitive function, including some clinical trials conducted to establish the activity[3][4]. There are adverse effects of Bacopamonnieri on humans, we can see about what it can do to rats.

Keywords: *Bacopamonnieri, Memory, Neurological disorders, Alzheimer's disease, Hypothermia,*

Introduction

Bacopamonnieri is an Indian folklore herbal medicine. In 1993, the Central Drug Research of India (CDRI) planned to start clinical trials using brahmi on human volunteers. They presented their research findings to numerous international brain research conferences. The research identified 2 active molecules: Bacoside A that assists in the release of nitric oxide allowing relaxation of the aorta and veins and blood to flow more smoothly through the body and aids circulation; and Bacoside B, a protein valued for nourishing nerve cells in the brain[5]. Subsequent studies showed that bacoside A and B were responsible for the cognition facilitating effect [6]. The aim of this study is to understand the features of Bacopamonnieri on memory.

Figure 1:Bacopamonnieri leaves

Chemical Components of Bacopamonnieri

Chemical constituents of Bacopamonnieri are mainly alkaloids Brahmin, herpestine, saponins, monnierins, hersaponin, bacoside–A and bacoside – B. Other constituents present in this plant are D- manitol,Betulic acid,B-sitosterol,Stigma sterol and its esters,Heptacosane,Octacosane,Nanocosane,Triacontane,Hentriacontane,Dotriacontane,Nicotin, 3-formyl – 4- hydroxyl – 2H pyran, Luteolin and its 7-glucoside, A-alanine, Aspartic Acid, Glutamic Acid and Serine[7].

Properties of Bacopamonnieri

This involves antispasmodic activity that the plant exhibited a tranquilizing effect in rat and dog. It caused smooth-muscle relaxation and showed antispasmodic activity [8, 9]. It also inhibits acetyl cholinesterase, activates choline acetyltransferase, and increases cerebral blood

flow [10]. Acetylcholinesterase, a major component of the central and peripheral nervous system, is ubiquitous among multi-cellular animals, where its main function is to terminate synaptic transmission by hydrolyzing the neurotransmitter, acetylcholine [11]. Prior studies on Bacopamonnieri on rats have shown that it improves the rate of learning in a brightness discrimination task and a conditioned avoidance task, that it improves retention, as demonstrated by savings in relearning, and that it attenuates amnesia induced by immobilization, electroconvulsive shock and scopolamine [12]. Anticancer, anti-ulcer, calcium antagonist, vasodilatory, smooth muscle relaxant, anti-addictive, and mast cell-stabilizing properties of Bacopamonnieri have also been demonstrated.There is a recent research that the anti-cholinesterase effect of Bacopamonnieri is a therapy for Alzheimer's disease in rats. Stress induced to rats is often studied to have inhibited hippocampal growth.

Hippocampus

The hippocampus, the brain's seat of memory, is located in the temporal (left and right) sides of the brain. It processes signals sent to the brain by the senses into the templates of memory, which are then stored in other parts of the brain, creating a long-term memory. Signals are converted into electrical impulses in the nerve cells due to a rapid change in protein composition. These impulses are conducted through the neurons and synapses. This process continues until the bonds between the nerve cells strengthen, and memory is created. Normal synaptic activity is a process mediated by neurotransmitters. Each neuron is a single nerve cell. It has one or more arms called axons that send signals (impulses) and one or more arms called dendrites that receive signals. When a signal is transmitted through an axon terminal,the vesicles fuse with its membrane. Neurotransmitters are released when the vesicles burst open into the synaptic space, the minute space between the sending and receiving cells used to discharge neurotransmitters. At the end of the signal, the axons reabsorb some neurotransmitters and the enzymes in the synapse neutralise the other neurotransmitters.

Improvement in the area of brain regions of a rat, affected by stress or severe disorders:

Alzheimer's disease (AD)

It is a slow progressive disease of the brain that is caused by impairment of memory and leading to disturbances in reasoning, planning, language, and perception. Alzheimer's disease (AD) is one of the most common forms of dementia affecting approximately 10% of the

population over the age of 65 years. Rats are similar to humans physiologically, genetically and morphologically. More importantly, the rat has a well-characterized behavioural display. Consequently, rat models of Alzheimer's diseaseshow accurate assessment of the pathology and novel therapeutics on cognitive outcomes. In a field of several theoretical options, the best approach has been the use of AChE inhibitors (AChEIs), which led to the introduction of tacrine as the first AChEI specifically approved for the treatment of Alzheimer's disease. Now, several kinds of AChEIs, such as donepezil,galantamine and rivastigmine are available for the symptomatic treatment of patients with mild to moderate Alzheimer's disease. However, these compounds have been reported to have the problems associated with the gastrointestinal disturbances and bioavailability. One of the most important approaches for treatment of this disease involves the enhancement of acetylcholine level in brain using AChE inhibitors [13]. Anticholinesterase activity of ethanol extracts of aerial parts of Bacopamonnieri are used in those studies. The ethanol extract of B. monnieri was found to contain saponins [14], mainly bacoside that has been used for memory and intellectual improvement. Subsequent studies showed that bacoside A and B were responsible for the cognition facilitating effect [6]. Other than facilitating learning and memory, these constituents in normal rats inhibited the amnesic effects of scopolamine, electroshock and immobilization stress [12]. Various experiments have identified potent antioxidant activity in Bacopamonnieri. Significant antidepressant activity has been observed in Bacopamonnieri extract using a rodent model of depression, comparable to imipramine after 5 days of oral administration. Additionally, anti-cholinesterase activity has been demonstrated [15][16]. Bacopamonnieri also demonstrates stress-decreasing activity in both acute and chronic stress situations. In a study the oral dose (100 mg/kg body weight) of ethanol extract of Bacopamonnieri inhibited acetyl cholinesterase (AChE) differentially in various brain regions viz. Cerebral cortex (51.6 %) > Cerebellum (51%) > Pons (44 %) > Thalamus (41.6 %) > Hippocampus (38.1 %) > Brain stem (34.3 %) > Striatum (24.9 %) [17]. Hippocampus is the major region of the brain belonging to the limbic system and plays an important role in epileptogenesis, memory and learning. The result demonstrated that the ethanol extract of Bacopamonnieri yields competitive inhibition in AChE kinetics in each Brain region of the rat. In a study, there is evidence of an antioxidant effect of Brahmi in the hippocampus[18]. The effect of the extract of Bacopamonnieri may be followed by antioxidant action within the hippocampus [19]. Central cholinergic system plays very important rolein regulation of cognitive functions. Loss of cholinergic neuronal in brain regions especially in hippocampal area is the major cause of Alzheimer's disease. The use of anti-cholinesterase in enhancement

of central cholinergic activity is presently the basis of treatment of dementia of Alzheimer's type [26].

Hypothermia on Rats

In a study, effect of BM was evaluated on acute stress (AS) and chronic unpredictable stress (CUS) induced changes in plasma corticosterone and monoamines-noradrenaline (NA), dopamine (DA) and serotonin (5-HT) in cortex and hippocampus regions of brain in rats. Treatment with BM (40 and 80 mg/kg) attenuated the stress induced changes in levels of 5-HT and DA in cortex and hippocampus regions [27]. The study involves the stress levels to cold exposure and oxygen levels on rats.When they had been pre-treated with Bacopa, these rats produced a protective protein, called a heat-shock protein, notably in hippocampus and cerebral cortex region. Bacopa helped these brain cell regions less susceptible to hypothermic and hypoxic stress by increasing the brain's protective enzymes storage. Bacopa somehow made those regions of the brain less susceptible to stress. In effect, it kept them in a relatively non-stressed state even in the presence of stress [20]. Stress goes with hand in hand on increased ascorbate demand because of its increased consumption and/or decreased synthesis and uptake [21]. Chronic stress-induced plasticity in the acute stress response may be important for stress adaptation, but may also contribute to pathophysiological conditions associated with stress. Thus, understanding the neural mechanisms underlying such adaptations may help us understand the aetiology of such disorders, and contribute to the future development of more effective treatment or prevention strategies. However, some data suggesting that differing plasma concentrations of ascorbic acid regulate in vivo steroid genesis by altering the activity of the membrane-bound enzyme adenylate cyclise. In spite of the fact that heat stress affected changes of AA in serum and adrenals, the same duration of cold exposure did not alter the concentration of AA in the liver, serum and adrenals. Here the results demonstrate that the exposure of rats to heat stress caused the ascorbic acid turnover e.g. the increase in the amount of ascorbate in blood due to the depletion of adrenals content, without de novo hepatic synthesis and support previous findings that heat is the stronger stressor in comparison to cold [22][23].

Conclusion

Hence Bacopamonnieri is used in indigenous systems of medicine for the treatment of various nervous system ailments such as insomnia, anxiety, epilepsy, and hysteria [24]. Preclinical and clinical studies have shown that BM improves memory and mental function.

It is believed that the components of BM extract aid in the repair of damaged neurons, neuronal synthesis, and the restoration of synaptic activity, and ultimately in nerve impulse transmission [25]. Bacopamonnieri has an adverse effect on rats on improvement in Alzheimer's disease and other clinical disorders. These experiments and researches make and provide a pathway in the treatment of complicated human disorders. We find that the active components of B. Monnieri i.e., bacoside A and B are the triterpenoid saponins and they may be responsible for the protective effect of this herb. Moreover, it seems that B. monniera extract possess certain additional antioxidative and neuroprotective properties due to which it may be used as herbal supplement for the treatment of neurodegenerative disorders and neuron degenerations [14].

Abstract

The increase prevalence of obesity will lead to a critical challenge to healthcare service. So it is necessary to examine the BMI in the early stage of pregnancy. As a result increase in the BMI at the time of pregnancy may leads to many critical problems and even it may leads to miscarriage or stillbirth. Excessive leanness and obesity are associated with different adverse pregnancy outcomes with major maternal and fetal complications.A pregnancy woman are underweight due to genetics, metabolism, lack of food or illness .Being underweight is associated with certain medical conditions, including hyperthyroidism, cancer or tuberculosis. People with gastrointestinal or liver problems may be unable to absorb nutrients adequately. Pregnancy women who are malnutrative underweight raise special concerns, as not only gross caloric intake may be inadequate, but also intake and absorption of other vital nutrients, especially essential amino acids and micro-nutrients such as vitamins and minerals

Key Words :*Pregnancy, body weight, BMI, Mass index, obese*

Introduction

Our BMI is calculated based on the relationship between our height and weight. As a result BMI above is used to determine whether the person are underweight, just right , overweight or obese .The expanding predominance of weight in young ladies is a noteworthy general wellbeing concern. These patterns majorly affect pregnancy results in these ladies, which have been reported by a few scientists. The rising rate of corpulence is a noteworthy general wellbeing worry in the West, where 28% of pregnant ladies are overweight and 11% are stout [1]. In the United States, the occurrence of weight in pregnancy changes from 18.5% to 38.3% as indicated by the definition utilized [2-5]. In the UK, 56% of all ladies are over the suggested BMI, with 33% of them named overweight (BMI > 25) and 23% corpulent (BMI > 30). In spite of the fact that the correct rate of corpulence in pregnant ladies in the UK isn't known, the Confidential Enquiry into Maternal and Child Health 2004 [6] announced that 35% of every single maternal passing happening in the triennium 2000– 2002 were in fat ladies with Body Mass Index > 30 Kg/m2. Pregnancy entanglements in overweight ladies were considered as ahead of schedule as 1945 [7].

From that point forward, various investigations have revealed a reasonable relationship between maternal overweight and antagonistic obstetric and perinatal results. Information from North America have been bolstered by comes about because of Danish [8, 9] and Swedish investigations [10, 11]. In the UK, Sebire [12] examined the impacts of maternal corpulence on pregnancy results in a London companion of 287,213 ladies. From that point forward, comparable reports have been distributed from Wales [13] and Scotland [14]. There are prior examinations that have explored the effect of maternal weight pick up amid pregnancy on chose obstetric results, e.g., macrosomia, meconium recoloring, cesarean conveyance rate, fetal development and gestational length. The vast majority of them were confined to maybe a couple maternal BMI classes or the impact of gestational weight pick up was dissected after changes for maternal prepregnancy BMI.

The impact of maternal underweight on obstetric execution is less clear. While a few specialists [15] have discovered expanded frequencies of preterm conveyance, low birth weight

and expanded perinatal misfortune in these ladies, others [16] have detailed a defensive impact of maternal underweight on certain pregnancy complexities and intercessions. Past research has discovered a solid relationship between expanding BMI and pregnancy prompted hypertension. A meta-examination of the danger of pre-eclampsia related with maternal BMI [17] demonstrated that the danger of pre-eclampsia multiplied with every 5 to 7 Kg/m2 increment in pre pregnancyBMI.Late surveys [18] on weight and pregnancy have featured a few issues pertinent to research and administration approach. Initially, the absence of standard meanings of overweight and heftiness makes correlation of discoveries crosswise over examinations troublesome. While most reports characterize stoutness as an expanded weight file of more prominent than or equivalent to 30 Kg/m2 (IOM), others have characterized it as expanded abdomen perimeter, expanded midsection – hip proportion or body weight of in excess of 90 Kg. This makes correlation of concentrates troublesome and may have suggestions in the administration of typical pregnancy, as in the United States, prescribed gestational weight pick up is subject to ladies' pre pregnancy BMI classifications [19].

BMI Calculation Formula

BMI = (Weight in pound / Height in inches ^{2}) x 703.
BMI = (Weight in kilograms / Height in meters ^{2}).

Based on the calculation of BMI every individual is analysis as underweight, normal weight, overweight, obese.

BMI of

1) Under 18.5 – you are considered underweight and possibly malnourished.
2) 18.5 to 24.9 – you are within a healthy weight range for young and middle-aged adults.
3) 25.0 to 29.9 – you are considered overweight.
4) Over 30 – you are considered obese.

BMI Category and Its Risk During Pregnancy

Underweight

Underweight is a term describing a human whose body weight is considered too low to be healthy. The definition usually refers to people with a body mass index (BMI) of under 18.5 or a weight 15% to 20% below that normal for their age and height group.

The previous Studies have demonstrated that some results of pregnancy are related with low pre pregnancy weight. They found that underweight ladies demonstrated expanded hazard for SGA, and low birth weight babies in contrast with ordinary weight patients. The biologic systems basic the relationship between maternal undernutrition status and slower foetal development and improvement stay theoretical. Ross et al. discovered that ladies with underweight had a littler plasma volume, lower cardiac output, increments in peripheral vascular protection, and lower rennin-aldosterone reaction in pregnancy contrasted and typical weight ladies. It appears to be likely that such lacking maternal hemodynamic changes might be related with uteroplacental inadequacy and the expanded pervasiveness of little for gestational age babies watched. Then again late research shows that movement of placental transport instruments might be specifically balanced by maternal sustenance. Direct lack of healthy sustenance amid pregnancy caused an expansion in maternal-foetal limit with respect to glucose transport, which was in any event somewhat clarified by an expansion in all out glucose transporter (GLUT) wealth. These reactions permit to manage typical fetal development, regardless of interminable maternal hypoglycaemia and a decline in the maternal-fetal angle in blood vessel plasma glucose fixation. Amid endless supplement lack the advancement of significant foetal hypoglycaemia supports the maternal foetal inclination in glucose focus by confining the turnaround exchange of glucose to the placenta, and decreasing placental glucose utilisation. There is prompted fetal gluconeogenesis, what outcome is lessened foetal tissue protein combination and easing back of foetal development to a rate that can be supported by the decreased placental supplement supply.

Causes and Effect

A Pregnancy woman are underweight due to genetics, metabolism, lack of food (frequently due to poverty), or illness .Being underweight is associated with certain medical conditions, including hyperthyroidism, cancer or tuberculosis. People with gastrointestinal or liver problems may be unable to absorb nutrients adequately. Pregnancy women with anorexia nervosa become underweight due to self-starvation (often accompanied by excessive exercise)[20].

Underweight might be secondary to or symptomatic of an underlying disease. Unexplained weight loss may require professional medical diagnosis. Underweight can also be a primary causative condition. Severely underweight individuals may have poor physical stamina and a weak immune system, leaving them open to infection[21][22]."Underweight status and micronutrient deficiencies also cause decreases in immune and non-immune host defenses, and should be classified as underlying causes of death if followed by infectious diseases that are the terminal associated causes.

Pregnancy women who are malnutrative underweight raise special concerns, as not only gross caloric intake may be inadequate, but also intake and absorption of other vital nutrients, especially essential amino acids and micro-nutrients such as vitamins and minerals. Incase pregnancy women, being grossly underweight can result in amenorrhea (absence of menstruation), infertility and possible complications during pregnancy. It can also cause anaemia and hair loss [23].

Over Weight

Overweight is generally defined as having more body fat than is optimally healthy. Being overweight is a common condition, especially where food supplies are plentiful and lifestyles are sedentary. Excess weight has reached epidemic proportions globally, with more than 1 billion pregnancy woman being either overweight or obese. Increases have been observed across all age groups.

A healthy body requires a minimum amount of fat for the proper functioning of the hormonal, reproductive, and immune systems, as thermal insulation, as shock absorption for sensitive areas, and as energy for future use. But the accumulation of too much storage fat can impair movement and flexibility, and can alter the appearance of the body [24].

The past investigations demonstrated that the high chances and complications of DM and hypertension previously and amid pregnancy are expanded in corpulent and overweight ladies. A meta-investigation investigating the relationship between gestational DM and BMI evaluated that the danger of creating gestational DM is two and four times higher among overweight and stout ladies individually contrasted and typical weight pregnant ladies. Insulin protection assumes a vital part in these pathologies. In normal weight ladies, pregnancy is as of now connected with a dynamic diminishing in insulin affectability amid the pregnancy. This metabolic change gives off an impression of being amplified in stout ladies. The fringe as well as hepatic insulin protection apparently is expanded in glucose-tolerant pregnant ladies, when contrasted and thin or normal weight women; fringe insulin affectability is 40% less in stout women.

As for the gestational and pre-gestational pathology, no measurably critical connections between heftiness or overweight and rehashed urinary tract diseases were watched. However different examinations, have shower an expanded frequency of urinary tract contamination in hefty pregnant women.

Causes and Effect

Being overweight is generally caused by the intake of more calories (by eating) than are expended by the body (by exercise and everyday living). Factors that may contribute to this imbalance include:

1. Eating disorders (such as binge eating)
2. Genetic predisposition
3. Hormonal imbalances (e.g. hypothyroidism)
4. Insufficient or poor-quality sleep
5. Limited physical exercise and sedentary lifestyle
6. Poor nutrition
7. Metabolic disorders, which could be caused by repeated attempts to lose weight by weight cycling

8. Overeating
9. Psychotropic medication (e.g. olanzapine)
10. Stress

So Pregnant women who are overweight or obese should speak with their health care provider about limiting weight gain and being physically active during pregnancy.

Obese

If a pregnancy woman are suffering from Obesity is stated as medical condition in which excess body fat has accumulated to the extent that it may have an adverse effect on health, leading to reduced life expectancy and/or increased health problems. Pregnancy woman are considered obese when their body mass index (BMI), a measurement obtained by dividing a woman's weight in kilograms by the square of the woman's height in metres, exceeds 30 kg/m2.

Indeed, even direct overweight is a hazard factor for gestational diabetes and hypertensive issue of pregnancy, and the hazard is higher in subjects with clear corpulence. Contrasted and ordinary weight, maternal overweight is identified with a higher danger of cesarean conveyances and a higher rate of sedative and postoperative intricacies in these conveyances. Low Apgar scores, macrosomia, and neural tube deserts are more successive in newborn children of fat moms than in babies of typical weight moms. The provincial dissemination of fat regulates the impacts of weight on starch resilience, hemodynamic adjustment, and fetal size. Maternal corpulence increments perinatal mortality .Long term intricacies incorporate compounding of maternal corpulence and advancement of weight in the newborn child. Previously established inclination directing, cautious pre-birth administration, tight checking of weight pick up, and long haul follow-up could limit the social and monetary results of pregnancies in overweight ladies.

Causes and Effect

Pregnancy women who is Obese increases the likelihood of various diseases, particularly heart disease, type 2 diabetes, obstructive sleep apnea, certain types of cancer, and osteoarthritis. Obesity is most commonly caused by a combination of excessive food energy intake, lack of physical activity, and genetic susceptibility, although a few cases are caused primarily by genes,

endocrine disorders, medications or psychiatric illness. Evidence to support the view that some obese pregnancy woman eat little yet gain weight due to a slow metabolism is limited; on average obese pregnancy woman have a greater energy expenditure than their thin counterparts due to the energy required to maintain an increased body mass[25].

Dieting and physical exercise are the mainstays of treatment for obesity. Diet quality can be improved by reducing the consumption of energy-dense foods such as those high in fat and sugars, and by increasing the intake of dietary fiber [21]. Anti-obesity drugs may be taken to reduce appetite or inhibit fat absorption together with a suitable diet. If diet, exercise and medication are not effective, a gastric balloon may assist with weight loss, or surgery may be performed to reduce stomach volume and/or bowel length, leading to earlier satiation and reduced ability to absorb nutrients from food.

Obesity is a leading preventable cause of death worldwide, with increasing prevalence in pregnancy woman and children, and authorities view it as one of the most serious public health problems of the 21st century. Obesity is stigmatized in much of the modern world (particularly in the Western world)[26], though it was widely perceived as a symbol of wealth and fertility at other times in history, and still is in some parts of the world. In 2013, the American Medical Association classified obesity as a disease

Effect of BMI during Pregnancy

If the BMI is high during the starting stage of pregnancy its lead to higher risk (ie If the body weight is over 100kg at the starting stage of the pregnancy and if the BMI is more than 35 than she should refer to an obstetrician[26].Being obese during pregnancy increase the risk of various pregnancy complication include

1. Gestational diabetes is refer to a woman who are obese during pregnancy will have diabetes.
2. Preeclampsia is refer to a woman who are obese during pregnancy will have high blood pressure

3. Infection is refer to a woman who are obese during pregnancy are at increased risk of urinary tract infection and it lead to high risk at the time of delivery

4. Thrombosis is refer to a woman who are obese during pregnancy will have a blood clot forms inside a blood vessel

5. Obstructive sleep apnoea is refer to a woman who are obese during pregnancy will have serious sleep disorder in which breathing repeatedly stops and starts

6. Pregnancy loss increase in BMI may even lead to miscarriage and stillbirth.

   So Pregnancy weight development was based on measurements generally carried out every fourth week during the first half of the pregnancy, every second week during weeks 20 to 32 and once weekly thereafter. Ninety-six percent of the infants were delivered between during Gestation week 36 to 42. Results presented demonstrate that data were not systematically biased by pregnancy duration.

Conclusion

Pregnancy outcome is worst in babies from mothers with low body mass index as compared to healthy weight mothers with respect to increased incidence of preterm birth, lower birth weight and increased neonate mortality on the neonatal ward.

To conclude, pregnancy complications related to maternal BMI is a growing problem. Both lean and obese mothers carry an increased risk of adverse perinatal outcome. Given the major economic and medical consequence of pregnancy in these women, all attempts should be made to maintain a normal BMI in women of childbearing age. Pre-pregnancy counseling, health programs and appropriate multidisciplinary management should be done. Last, we acknowledge the small sample size as being a weakness of the present study, but this was due to it being a prospective Study carried out in one unit of a tertiary care teaching hospital over a period of 1 year only, with many exclusion criteria.

Effects of vitamin D on Bones – A Review.

Sangavi R [1], Anitha Roy [2], Aravindh Kumar [3]

Graduate student[1] ,Senior Lecturer [2], Department of Biochemistry

Professor [3], Department of Orthodontics

Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences,

Saveetha University, Chennai, India

Abstract:

Vitamin D refers to a group of fat-soluble secosteroids responsible for enhancing intestinal absorption of calcium, iron, magnesium, phosphate and zinc. Cholecalciferol and ergocalciferol can be ingested from the diet and from supplements. The body can also synthesize vitamin D (specifically cholecalciferol in the skin, from cholesterol, when sun exposure is adequate hence its nickname, the "sunshine vitamin". This article summarizes the beneficial and importance of the Vitamin D and its action on bone.

Keywords:*Vitamin D, Hormone, Calcium, Osteoporosis, 24-25 dihydroxycholecalciferol.*

Introduction:

Vitamin D is a vitamin. Found in small amounts in foods like fatty fish such as herring, mackerel, sardines and tuna. In humans, the most important compounds in this group are vitamin D_3 (also known as cholecalciferol) and vitamin D_2 (ergocalciferol)[1].Vitamin D is made more available by adding it to dairy products, juices, and cereals known as “fortified with vitamin D.” But most vitamin D what the body gets is obtained through exposure to sunlight. Vitamin D can also be made in the laboratory as medicine. Vitamin D is used for preventing and treating rickets

which is a disease caused due to lack of vitamin D .Vitamin D is used in treatment of weak bones in cases like osteoporosis and also bone loss seen in conditions like hyperthyroidism. It is also used for preventing fractures in people who are at risk for osteoporosis and prevents low calcium and bone loss in people with kidney failure. Vitamin D is used for conditions of the heart and blood vessels, including high blood pressure and high cholesterol.

Dietary Sources:

Vitamin D is found in few dietary sources [2]. Sunlight exposure is the primary source of vitamin D for majority of people, other than supplements [3].

Vitamin D_2

Main article: Ergocalciferol

Fungus as obtained from USDA nutrient database (per 100 g) [4]. Low values in mushrooms for vitamin D below indicate incidental exposure to sunlight which activates synthesis of vitamin D2. Vitamin D levels can be controlled at much higher levels especially when fresh mushrooms or dried powders are purposely exposed to artificial sunlight with the use of an ultraviolet lamp [5]

- Mushrooms, portabella, exposed to ultraviolet light, raw: Vitamin D_2: 11.2 µg (446 IU)
- Mushrooms, portabella, exposed to ultraviolet light, grilled: Vitamin D_2: 13.1 µg (524 IU)
- Mushrooms, shiitake, dried: Vitamin D_2: 3.9 µg (154 IU)
- Mushrooms, shiitake, raw: Vitamin D_2: 0.4 µg (18 IU)

Vitamin D2 known as ergocalciferol which is found in fungi, is synthesized from viosterol when ultraviolet light stimulates and activates ergosterol.

Mushrooms enhanced with Vitamin D2 due to Ultraviolet irradiation have same bioavailability as compared to other Vitamin D2 supplement in humans. Vitamin D2 from UV-irradiated yeast baked into bread or mushrooms is bioavailable and increases blood levels of 25(OH) D.[6]

Plants

- Alfalfa (*Medicago sativa subsp. sativa*), shoot: 4.8 µg (192 IU) vitamin D_2, 0.1 µg (4 IU) vitamin D_3 (per 100 g).[7]

Vitamin D_3

Main article: Cholecalciferol

Staple foods are artificially fortified with vitamin D is practiced in some countries.

- Vegan sources

*lichen

*Vitamin D3 contents range from 0.67 to 2.04 µg g^{-1} dry matter in the thalli of C. arbuscula specimens grown under different natural conditions.[8]

- Animal sources[9]
  - Fish liver oils, such as cod liver oil, 1 Tablespoon (15 ml) provides 1,360 IU (90.6 IU/ml)
  - Fatty fish species, such as:
    - Catfish (wild), 85g (3 oz) provides 425 IU (5 IU/g)
    - Salmon, cooked, 100g (3.5 oz) provides 360 IU (3.6 IU/g)
    - Mackerel, cooked, 100g, 345 IU (3.45 IU/g)
    - Sardines, canned in oil, drained, 50g (1.75 oz), 250 IU (5 IU/g)
    - Tuna, canned in oil, 100g, 235 IU (2.35 IU/g)
    - Eel, cooked, 100g, 200 IU (2.00 IU/g)
  - A whole egg provides 20 IU if egg weighs 60g (0.333 IU/g)
  - Beef liver, cooked, 100g, provides 15 IU (0.15 IU/g)

Molecular Mechanism Of Vitamin D Action:

The hormonal metabolite of Vitamin D, Vitamin D_3 (1,25D) binds to the Vitamin D Receptor (VDR) and initiates biological responses. When occupied by 1,25D, VDR interacts with the Retinoid X Receptor (RXR) to form a heterodimer that binds to vitamin D responsive elements in the region of genes directly controlled by 1,25D. Ligand-activated VDR-RXR modulates the

transcription of genes encoding proteins which regulates the functions of vitamin D which is signaling intestinal calcium and phosphate absorption to affect skeletal and calcium homeostasis with the help of complexes like coactivators and corepressors. Action of Vitamin D depends on expression of adequate VDR and RXR co receptor proteins and cell-specific programming of transcriptional responses to regulate select genes that encode proteins that function in mediating the effects of vitamin D.

Vitamin D is widespread in nature, and one of its roles in vertebrate animals and humans is to promote the absorption of calcium and phosphate to enable normal mineralization of the skeleton [10]. Vitamin D deficiency in childhood makes children prone to rickets where defective mineralization of growth plate cartilage and bone leads to morphologically altered long bones, resulting in curvature and deformation [11]. Osteomalacia is a condition where the bone matrix fails to mineralize, resulting in bone pain, muscle weakness and increased risk of bone deformation and fracture which occurs as a result of vitamin D deficiency in adults [12]. The characteristic feature of a vitamin D deficiency is a low serum 25(OH) D [13] concentration, which is associated with decreases in both serum 1, 25-(OH) 2D [14]. In turn, low serum calcium results in increased secretion of parathyroid hormone (PTH)which promotes the production of 1,25-(OH) 2D [15]. As a result, serum concentrations return to normal but are accompanied by higher serum concentration of PTH, indicative of secondary hyperparathyroidism [16]. Increases in serum PTH concentration have been reported to stimulate the rate of bone turnover, causing a reorganization of the bone structure [17]. Hence, secondary hyperparathyroidism has been demonstrated as the predominant factor by which vitamin D deficiency results in increased susceptibility to bone fractures.

Vitamin D And Bone Formation:

Treatment of rachitic chicks with 1-hydroxyvitamin D3, the synthetic analogue of 1,25-dihydroxyvitamin D3, does not prevent most of the changes seen in bone affected by rickets, in spite of normal plasma levels of calcium and inorganic phosphate (unpublished). Similar findings have been reported for man [18], suggesting that vitamin D affects bone formation directly and that the effect is mediated by a metabolite(s) other than 1, 25-dihydroxyvitamin D3. In normocalcaemic animals, the predominant dihydroxylated metabolite of vitamin D in the

blood is 24, 25-dihydroxyvitamin D and, like 1,25-dihydroxyvitamin D, it is synthesised in the kidney[19][20]; but nothing is known of its function. Improved calcium retention has been reported in anephric patients treated with 24, 25-dihydroxyvitamin D3, which has been observed to accumulate preferentially in fetal bones of rat [21] and in callus tissue formed after experimental fracture (unpublished). It reports that when rachitic chicks are exposed to various therapeutic treatments with metabolites of vitamin D, the presence of 24, 25-dihydroxyvitamin D is essential for the healing process.

Vitamin D And The Actions Of Its Metabolites On Bone:

The vitamin D endocrine system has clear beneficial effects on bone as demonstrated by prevention of rickets in children and by reducing the risk of osteomalacia or osteoporosis in adults or elderly subjects. Depending on the design of the study of genetically modified animals, however, 1, 25(OH)2 D and the vitamin D receptor (VDR) may have no effect, beneficial or even deleterious direct effects on bone. In case of sufficient calcium supply, vitamin D and its metabolites can improve the calcium balance and facilitate mineral deposition in bone matrix largely without direct effects on bone cells, although some beneficial effects may occur via mature osteoblasts, as demonstrated in mice with osteoblast-specific overexpression of VDR or 1α-hydroxylase [22]. In case of calcium deficiency, however, 1, 25(OH) 2 D enhances bone resorption, whereas simultaneously inhibiting bone mineralization, so as to defend serum calcium homeostasis at the expense of bone mass. This dual role probably provides a survival benefit for land vertebrates living in a calcium-poor environment.

Vitamin D has a well-recognized role in bone biology, being required for normal bone formation and normal mineralization. The uncertainty that will be addressed in this review is how much of its effects on bone are secondary to its actions on gut calcium and phosphate absorption and how much relate to direct effects on bone. Moreover, if there are effects directly on bone, how much of any bone activity is on bone formation and how much on bone resorption. Conflicting data suggest that these actions may differ by timing, skeletal site and dietary calcium intake.

In the invivo studies, in vitamin D receptor knockout (Vdr−/−) models, there was the expected phenotype similar to various forms of vitamin D-deficient or -resistant rickets. There were

similar phenotypes in models of knockout of the 1α-hydroxylase (CYP27B1) enzyme. The findings in these studies underpin the critical role of vitamin D in normal calcium and bone/tooth/growth plate homeostasis. Vitamin D is generally associated not only with improved bone mineralization but also with increased bone resorption, and thus may seem to represent 'good' and 'bad' effects on bone. *In vitro* studies have readily demonstrated bone resorbing effects responses to 1, 25-dihydroxyvitamin D3 (1, 25(OH) 2D3) [23],

Interactions between cells of the osteoblast and osteoclast lineages, including osteocytes and possible role of chondrocytes. The regulatory pathways between osteoblasts and osteocytes and osteoclasts include multiple negative (red) and positive (green) feedback loops as indicated; all potentially modifiable by 1,25(OH)2D3. These include release of matrix components, such as transforming growth factor-β (TGFβ) and bone morphogenetic proteins (BMPs) that influence osteoblast activity, and humoral factors that influence mineral homeostasis at distant sites, such as fibroblast growth factor (FGF)-23 on renal phosphate handling. Given these loops, any regulatory effect on one cell type can influence the others. Chondrocyte effects on surrounding cells are also potentially involved. The complexity of these inter-relationships may explain the differential effects of 1, 25(OH) 2D3 in driving anabolic and catabolic outcomes. RANKL, receptor activator of nuclear factor-κB ligand [24].

Role Of Vitamin D In Bone Homeostasis:

One way to bring the divergent data on vitamin D and bone into a unifying hypothesis is to look at the evolution of vitamin D in vertebrates published in first issue (January 2014) of *BoneKEy Reports*) [25]. The vitamin D endocrine system has already been identified in early fish such as lamprey but still without any detectable effect on calcium and certainly not on the still nonexistent mineralized bone. In at least some late teleosts, vitamin D metabolites via VDR probably stimulate a positive calcium balance (possibly more in gills than in the intestine with TRPV channels as mediator). This seems logical as to allow the building up of a large bone structure (mainly acellular, thus without osteocytes and without multinuclear osteoclasts). This is apparent in all amphibians tested, and such an evolution would be logical as terrestrial animals

face a calcium-poor environment. So from this early stage in the evolution of vertebrates onwards, the role of vitamin D would be to enhance a positive external calcium balance. From amphibians onwards, PTH becomes a calcium-regulating hormone using bone as a calcium reservoir in times of shortage of nutritional calcium. Whether the vitamin D hormone is already cooperative with PTH to stimulate osteoclastogenesis and bone resorption in amphibians is plausible but needs further exploration. From reptiles onwards, a new dimension is added: a complex system is developing to regulate bone mineral deposition, with hormonal and local regulation of SIBLING proteins, several enzymes such as PHEX and a complex regulation of pyrophosphate PPi. Most of these factors are under the control of 1, 25(OH) 2D3 and have, as net result, an inhibition of mineralization. This is not illogical as high 1, 25(OH) 2D3 with PTH represents the first-line defense against a low nutritional calcium supply by increasing both fractional intestinal absorption and renal calcium reabsorption. Enhanced bone resorption and simultaneous inhibition of mineral deposition can thereby avoid a futile cycle of calcium resorption from bone and its immediate reuse for mineralization of bone.

Therefore, in the first place, the effect of vitamin D action would be to defend systemic calcium homeostasis by making calcium available for the extracellular fluid pool from the intestine if possible but from any internal source if required. In case of very low external calcium supply, high levels of 1, 25(OH) 2D3 would use the bone calcium reservoir for serum calcium homeostasis at the (temporary) expense of bone mass and strength. From a teleological standpoint, this seems a logical strategy as later access to nutritional calcium could then allow the rebuilding of the skeleton. Thus 1, 25(OH) 2D3 acting through the VDR may favor replication and maintenance of immature cells of the osteoblast lineage. These roles may be critical for bone resorption and ‘preventing’ futile bone mineralization under conditions of calcium stress. On the other hand, during a ‘recovery’ phase, 1, 25(OH) 2D3 acting through the VDR acting in more mature cells may encourage terminal differentiation of mineralizing cells. Consistent with studies of action of 1, 25(OH) 2D3 on osteoblastic cells at different stages of their maturation [26]. This may provide a drive to re-mineralization of the skeleton after surviving the calcium stress situation. This divergence between sacrifice of bone for calcium homoeostasis and rebuilding of the skeleton at other times is not dissimilar from the catabolic effect of chronically high PTH levels versus the anabolic effect of transiently high PTH levels.

Phosphate homeostasis is quite different from that of calcium as terrestrial animals live in a relatively phosphate-rich environment in comparison with marine animals. A phosphaturic hormone (or hormones) may therefore be more important than hormones stimulating phosphate uptake in the intestine or kidney. Although 1,25(OH)2D3 clearly stimulates phosphate uptake in the gut, the VDR endocrine system in the intestine seems to be redundant as selective Vdr−/− in the intestine does not modify serum or urinary phosphate concentration and therefore such animals do not show the typical growth plate abnormalities seen in vitamin D, calcium or phosphate deficiency.

That vitamin D has both beneficial and deleterious effects on bone are not an exception for ligand of nuclear receptors, such as estrogens, androgens or glucocorticoids. In fact, for each of these nuclear receptors it has allowed the development of structural analogs of the natural hormone that have more beneficial and less deleterious effects (for example, selective estrogen receptor modulators [DeLuca [27]]).

Vitamin D And Sclerostin:

Objective Serum sclerostin levels have been reported to be inversely associated with serum 25OHD levels, but the effect of vitamin D and calcium supplementation on serum sclerostin levels is unknown. Men and women appear to have different serum sclerostin responses to vitamin D and calcium supplementation [28].

Role Of Vitamin D In Healing Of Fracture:

Fracture healing is a process which involves response to injury, intramembranous bone formation, endochondral bone formation, and bone remodeling in order to restore the tissue to its original physical and mechanical properties. All this process is influenced by a variety of systemic and local factors. Vitamin D is said to play an intimate role in healing fracture, but very little data exists on how it does. Report suggests that the hypovitaminosis D is a possible cause of inadequate fracture healing and re fracture in children and it shows a clear effect of vitamin D supplementation on calcium.

Conclusion:

A greater understanding of how the local synthesis and activity of vitamin D within the bone micro-environment will contribute to the rationale for vitamin D and calcium supplementation. Vitamin D activities in bone provide evidence of actions regulating important aspects of bone mineral metabolism, integration of the evidence from the endocrine and autocrine activities of vitamin D are required to establish these strategies in the future.

Abstract:

Oral candidiasis is a fungal infection caused mostly by the species Candida albicans along with other causative agents like Candida tropicalis, Candida glabrata, Candida parapsilosis etc. The three main groups of candidiasis are acute, chronic and angular. The treatment involve the antifungal drugs like nystatin, miconazole and Amphotericin B. The recent advances in elucidating the interaction between the candidia organism and the environment are cellular and molecular mechanism. Polymerase chain reaction analysis, recombinant antigen technique and candida biofilm communication have found the existence of oral candidiasis. Traditional and innovative treatment modes are done to mange oral candidiasis.This review is done to learn about the advanced and emerging technique in the diagnosis and treatment of oral diagnosis.

Key Words : *fungal infection , oral lesion, Candida, advanced techniques , anti- fungal.*

Introduction:

Oral candidiasis is a significant and a familiar infection . Candida albicans is a most common fungal pathogen[1]. It is present in both pathogenic and non pathogenic states and has been able to develop a myriad of powerful mechanisms that allows for thriving colonisation and subsequent infection if the host under appropriate conditions . Candida albicans is an important pathogen that us capable if causing localised intra oral candida infection , but one that can permeate and initiate systemic effects as well [2,3]. It is considered the most important of the candida species and can be found in all areas of the mouth and on the surface of dentures. The fungi that cause oral candidiasis are considered as a part of the normal flora of the mouth [4]. Intra oral candidiasis can be based on the clinical recognition of a particular form of candida. Various clinical manifestations of oral candidiasis are present including pseudomembranous candidiasis , hyperplastic candidiasis (candidal leukoplakia), atrophic candidiasis , acute and chronic erythematous and angular cheilitis [8,9]. In addition to the clinical forms of candida for diagnosis , there are also various species of oral candida present . Some of the species commonly seen intra orally are c.albicans , c.glabarata, c.krusie, c.stellaroidea, c.tropicalis[7,8]. The main objective of this paper is to evaluate advances in the cellular and molecular mechanisms involved in the diagnosis and identification of oral candidiasis and assess the diverse novel treatment modalities for oral candidiasis in the clinical setup . Various cellular and molecular mechanisms have been employed that helps to elucidate the interactions between candida organisms and their environment [8,9]. Polymerase chain reaction analyses, candida biofilm communication , and recombinant antigen techniques have been found to facilitate explanation of the endurance and endurance and existence of oral candidiasis , specifically c.albicans. Various modes of treatment , both traditional and innovative are used utilised to manage oral candidiasis [9,10].

Cellular and Molecular Mechanism used in Oral Candidiasis for the Diagnosis of the Candida Species

The oral candida organism adhere to the oral mucosa and to the non-oral surface via the use of biofilms and it allows the species to grow and flourish[11]. Candida continues to grow in the mouth because they exist in mixed biofilms , where they can live together with bacteria and successfully live in those environments[12]. The cell wall structure if candida shows the properties that promote the formation of biofilms , thereby allowing it to infiltrate the tissue and ultimately inhabit various organs in the body, including the oral mucosa[14,15]. They have special mechanisms that allow them to switch back and forth from one form to another (from budding yeast from to pseudohyphal to hyphal forms. The formation of the candida biofilms creates serious clinical injurious effects because of their increased resistance to antifungal therapy . This property to adhere to the host cells of the epithelium is the virulence Factor of species of oral candidia. Additionally , it has been found that candida species and bacteria will communicate with each other by a mechanism called quorum-sensing[14,16]. The Candida albicans has two major quorumsensing molecules they are tyrosol and farnesol. Tyrosol stimulate the formation of hyphae in C.albicans and farnesol inhibits the shift from the yeast form to the hyphal form and regulates the structural morphology of the cell [16,17]. Quorum is a sensing phenomenon where the accrual of signalling molecules enables a single cell to sense the number of bacteria/fungi which are present.

Polymer Chain Reaction (PCR) Fingerprinting Method

Polymerase Chain Reaction (PCR) fingerprinting has been used to differentiate between various strains of C. Albicans and C. dubliniensis. This is a great problem because of the high degree of similarity in the phenotype between C. dubliniensis and C. Albicans [18]. Multiplex PCR has been used to identify various species, particularly C. Albicans, C. glabrata, and C. tropicalis[19].PCR has been successfully used to identify C. dubliniensis in gingival fluid of healthy individuals with periodontal disease [20]. Tests were

identified using conventional sampling methods as well as specific PCR assays. Results showed that C. dubliensis was isolated and identified in subgingival fluid of periodontal pockets of persons having healthy immune systems. Realtime PCR and lucigenin-based chemiluminescence have showed that Candida biofilms can exert resistance to many commonly employed antifungal in the clinical setup [21]. Real-time PCR chemistries allow for the detection of PCR amplification during the early phases; measuring the kinetics during the early phases provides an advantage over the traditional PCR where agarose gels are used for the detection of PCR amplification at the final endpoint phase of the reaction. C. Albicans genes have been identified that regulate the communication between oral epithelial cells in oropharyngeal candidiasis and vascular endothelial cells [22]. These genes increase their interaction as they come into contact with epithelial and endothelial cells and as they endure the stresses that they likely encounter as they grow in the oropharynx and in the blood. C. Albicans has a an assortment of pathogen-associated molecular patterns; recognizing this array of patterns on the cell wall of C. Albicans is mediated through many pattern-recognition receptors such as the Toll-like receptors [27]. These Toll-like receptors are a separate family of pattern-recognition receptors that help to recognize microbes and eventually activate phagocytosis and inflammatory responses. Various techniques have been used to identify Candida species. Multiplex PCR was used to quickly identify Candida species in samples of oral rinses without having to use an additional step of extraction in the process; ten species were identified in just a few hours [28]. Species that were identified included C. albicans, C. krusei, C. parapsilosis, C. famata, C. dubliniensis, C. kefyr, C. tropicalis, C. glabrata, C. guillermondii, and C. lusitaniae.

Immuno Flurosense Method

Use of recombinant antigens for the diagnosis and treatment of invasive candidiasis has been recently studied. The detection of antibodies directed against antigens which are expressed on the C. albicans germ tube surface by indirect immunofluorescence has been shown for diagnosis. Among the Candida enzymes detected in sera of patients who have systemic candidiasis, enolase has been found to be diagnostic. Advances in molecular

biological techniques have also allows completion of the Candida albicans genome sequence.These molecular biology techniques have allowed the production of recombinant antigens which are useful for the discovery and identification of antibodies against them. It has been shown that the detection of antibodies against purified and well-defined recombinant antigens allows for the diagnosis of Candidal organisms which are invasive in nature [23].

Gene Profiling Techniques

Host-fungus interactions were analyzed using a combination of microscopic, cellular and molecular techniques as well as an in vitro RHE (reconstituted human oral epithelium) model of oral candidiasis so to scrutinise the Candida infection process [24]. It was found from this research analysis that morphology and adaptive response of Candida organisms play important roles in the way the host and the fungus respond to one another if there is an infection. Candida has also been found by the study of structural mucosal and innate immune cells [25]. The activation of mechanisms which are protective in nature in both immune and non-immune effector cells depends on appropriate recognition of pathogens. Pattern-recognition receptors expressed on host cells allow for the rapid recognition of pathogens [26].

Immunological Methods

Denture stomatitis is a very real and common problem encountered within the dental setting; a significant emphasis has been placed in this review in both the immunology as well as in the treatment because of the practical implications that this topic carries for the general as well as specialty dental practitioner. In a denture-related stomatitis study, the main yeast strain isolated by far was C. Albicans. In the denture-related stomatitis group (versus the non-denture related stomatitis group), there were a greater variety of strains of Candida which were identified via microbiological sampling [29]. Candida mannan antigen detection was found to be a reliable as well as a sensitive method for the serologic diagnosis of systemic candidiasis [30]. The kit used in the study utilized an ELISA (Enzyme Linked Immunosorbent Assay) using polyclonal antibodies against Candida albicans mannan; the results revealed that the mannan assay had high positive

results for Candida in comparison to the standard of the culture medium. Denture stomatitis is a very real and common problem within the dental setting and a significant portion of this has been reviewed here with regards to immunologic aspects. It was noted in another investigation, that C. Albicans is the predominant fungal species isolated from those who wear dentures and that C. dubliniensis was isolated from the underlying mucosa but not from the prosthetic surface [31]. C. glabrata has been found to be an opportunistic pathogen in individuals who use long term immunosuppressants and broad-spectrum antibiotics-especially in the elderly [32]. This may be due to several factors, including decreased salivary gland hypofunction as well as pH changes noted in the elderly.

Microbial Culture

Identification of Candida species has been examined using CHROMagar[33]. CHROMagar can differentiate C. albicans as green colonies, C. krusei as pink colonies and C. tropicalis as blue colonies. Candida species were isolated and identified using this agar from HIV patients with oropharyngeal candidiasis. C. albicans and C. krusei were identified with a few strains of C. tropicalis. A few strains of C. tropicalis generated colonies with a trace of a greenish color making it complicated to differentiate it from C. albicans. In another identification and treatment analysis, fifty-five patients with complete upper dentures were examined before and after the use of a ten percent vinegar solution. Vinegar solution was used to disinfect their denture. Before the use of the solution, C. albicans, C. glabrata, C. krusei, C. lusitaniae, C. guillermondii, C. tropicalis, and C. parapsilosis were identified [34]. After the use of the vinegar solution, C. guillermondii, C. lusitaniae, and C. parapsilosis were not detected; all the other strains of Candida were still present. In a previous retrospective study of Candidal colonization and removable denture prostheses, forty-four patients exhibited various Candidal counts with respect to four groups of species: C. albicans, C. krusei, C. tropicalis, and unspecified Candidal species. The frequency of C. albicans was 87 percent with prostheses versus 90 percent without prosthesis; unspecified Candidal species was 58 percent versus 60 percent, C. krusei 14 percent with prosthesis versus 13 percent without prostheses, while the frequency of C. tropicalis was 6 percent for both.

Treatment of Oral Candidiasis

Various traditional modes of treatment have been used to manage oral candidiasis. Treatment can be accomplished with the use of appropriate antifungal medications and routine disinfection of removable intraoral prostheses [35]. Both topical and systemic medications have been used. Topical agents include Nystatin oral suspension and nystatin oral powder as well as clotrimazole troches. Systemic antifungals can be given by prescription and include itraconazole, ketoconazole, and fluconazole. Mycostatin® is a brand name for nystatin solution. Medications specifically for the treatment of angular cheilitis include nystatin ointment, miconazole cream (2%), and clotrimazole cream (1%). Disinfection of oral appliances can be accomplished via the use of Chlorhexidine and nystatin solution. (2% chlorhexidine gluconate, Peridex) [36]. Newer antifungals in the prophylaxis and maintenance of oral candidiasis therapy for invasive fungal infections include Posaconazole, Ravucanazole, and Echinocandins such as Caspofungin, Micafungin, and Anidulafungin[37]. They all have been found to be less toxic antifungal alternatives to Amphotericin B. Posaconazole was approved in 2006 for the treatment of invasive Aspergillosis and Candida infections. Ravucanazole is highly effective against a variety of fungi, including Candida pathogens and has been used to treat esophageal candidiasis in HIV (human immunodeficiency virus) patients. Caspofungin has inhibitory effects against various Aspergillosis and Candida species. Micafungin has been shown to be highly effective against esophageal candidiasis and has fewer side effects than Caspofungin. Anidulafungin is the newest echinocandin and appears to be very effective against many Candida species in vitro. Anidulafungin was found also to be more efficacious in one study than the traditional form of systemic fluconazole for the treatment of invasive candidiasis [38]. Recent developments in the treatment of oral candidiasis include the use of probiotic bacteria which are known to reduce the growth of pathogenic microbes [39]. A recent study used cheese containing a mixture of probiotics such as Lactobacillus rhamnosus GG, Lactobacillus rhamnosus LC705, Propionibacterium freudenreichii and shermanii JS. The use of probiotic cheese revealed

the reduction of the prevalence of oral Candida in the elderly and its use also allowed for the reduction of the prevalence of hyposalivation.

Another group of elderly individuals were evaluated for possible reduction of Candida overgrowth with the use of an amine fluoride-stannous fluoride mouth rinse and toothpaste combination. The number of elderly with high Candida albicans counts decreased after use of the combination. Other Candida counts (non-albicans) were also low in the participants of the study. In another novel application, fluconazolemucoadhesive buccal films were prepared and placed in the buccal mucosa where the drug was released over a five hour period and ultimately the disc eroded away. This topical method was used as another alternative to the traditional form of systemic fluconazole and seemed to reduce side effects of the medication that may have been encountered in the systemic form. There has been current acceptance by the FDA for the miconazole Lauriad in a mucobuccal tablet form to treat oropharyngeal candidiasis in a once-a-day dosing format [40]. In a different treatment of denture stomatitis, dentureliner containing nystatin was placed for a period of one week. This was compared to a denture-liner filled with nystatin and left on the denture surface for four days. Dentures left with nystatin containing denture liner for four days had higher yeast counts than those that were left in place for one week. Salivary yeast counts were much lower for individuals who had a denture liner that contained nystatin as the antifungal than individuals who did not use a denture liner containing an antifungal. These and other recent advances have allowed the practitioner to treat various forms of Candida species in an effective manner in the clinical setting.

Conclusion

Oral candidiasis is a fungal infection caused mostly by the species candida albicans along with the other causative agents like candida tropicalis, candida glabarata etc. The treatment involves the antifungal drugs like nystatin, miconazole and amphotericin B.

The recent advances that help in the diagnosis and treatment of oral candidiasis are cellular and molecular mechanisms, polymerase chain reaction, recombinant DNA, reconstituted human oral epithelium, immunological methods which allows the practitioner to treat various candida species in an effective manner in the clinical setting.

Abstract

Tooth development or odontogenesis is the complex process by which teeth form from embryoniccells, grow, and erupt into the mouth. Although many diverse species have teeth, non-human tooth development is largely the same as in humans. For human teeth to have a healthy oral environment, enamel, dentin, cementum, and the periodontium must all develop during appropriate stages of fetal development. If the teeth do not start to develop at or near these times, they will not develop at all, resulting in hypodontia or anodontia. These anomalies not only affect the esthetic appearance of teeth but also pose difficulties during dental treatment and sometimes are the cause of dental problems Dental anomalies are clinically evident abnormalities. They may be the cause of various dental problems.Careful observation and appropriate investigations are required to diagnose the condition and institute treatment.In this review, we describe the various developmental anomalies of tooth based on size,shape, number, and structure.

KeywordsOdontogenesis; Developmental anomaly; Esthetics; Dental management

Introduction

Developmental dental anomalies are prominent deviations in the form of normalcolor, contour, size, number, and degree of development of teeth. Local as well as systemic factors may be responsible for these developmental disturbances.The deciduous teeth begin their formation between the sixth and eighth week of prenatal development, and permanent teeth form around the twentieth week[1] Such influences may begin before or after birth, hence deciduous or permanent teeth may be affected. Aberrations in the normal number of teeth include supernumerary teeth (hyperdontia), i.e. excess teeth or hypodontia (teeth missing from the normal compliment) while oligodontia is a developmental absence of six or more teeth excluding the 3rd molars.[2]

Anomalies of shape of teeth include microdontia and macrodontia. Microdontia refers to teeth that are physically smaller in size than usual and macrodontia in turn refers to teeth that are physically larger in size than normal. Anomalies of shape include dens invaginatus (DI), talon cusp, dens evaginatus, gemination, fusion, root dilacerations, taurodontism, and concrescence.It is an anomaly resulting from invagination in the surface of a tooth crown or rarely the root and which is lined by enamel and dentin[3] Dens evaginatus is a focal area of the crown, projecting outward and giving rise to a horn-like protuberance on the affected surface that appears as an extra cusp [4] Talon cusp is an accessory cusp usually located on the lingual surface and rarely on the facial surface of permanent or deciduous incisors. It arises from the cingulum area, or cemento-enamel junction (CEJ) of maxillary or mandibular anterior teeth, in both the primary and permanent dentition [5].Fusion and gemination have been referred to as double teeth which appear as larger than normal sized teeth. Gemination is defined as a single enlarged tooth or joined (double) tooth in which the tooth count is normal when the anomalous tooth is counted as one [6].Fusion is defined as a single enlarged tooth or joined (double) tooth in which the tooth count reveals a missing tooth when the anomalous tooth is counted as one [7].

Taurodontism is a developmental anomaly that usually affects the molars in which the body of the affected teeth is very large and the associated roots are shortened, with bifurcation near the apex.Concrescence may be the Uni for two contiguous teeth Toward cementum. Dilaceration will be a abnormal twist in the root alternately crown of a tooth rot. The twist is that's only the tip

of the iceberg incessant in the root Be that might be exhibit anyplace along those length of the tooth root[8].

These anomalies not only affect the esthetic appearance of teeth but also pose difficulties during dental treatment and sometimes are the cause of dental problems. The present study was performed to evaluate the frequency of occurrence of dental anomalies of size, number, and shape in the adult population and their implications in the treatment of such conditons[9].Thongudomporn and Freer (1998) reported that 74.77% of their subjects had at least one anomaly. The most prevalent anomaly was invagination, while supernumerary teeth and root dilacerations were the least frequent anomalies.Early endodontic management of tooth can preserve the tooth.

Anomalies of Teeth

They are various types of anomalies based on the size and shape of teeth.

Hyperdontia and it's Management

Various reports of hyperdontia are mostly in children but it is increasingly common in patients with cleft lip and cleft palate. Salcido-garcía et al have reported a higher prevalence in males than in females.Among the various supernumerary teeth, mesiodens are the most commonly found followed by 4^{th} molars, premolars and maxillary lateral incisors [10]There was a higher occurrence of paramolars followed by mesiodens and supernumerary teeth in the anterior region. Impacted supernumerary teeth had equal occurrence in maxilla and mandible and occurred in the anterior rather than the posterior region.It can be managed orthodontically by extraction and root canal treatment of additional teeth.

Hypodontia and its Management

This occurs in permanent dentition in 0.3% of the population.Congenitally missing teeth most commonly occur with maxillary laterals, 2^{nd} premolars and mandibular central incisors and can be unilateral or bilateral[11]. Radiographs confirm the absence of missing teeth. The etiology is believed to be hereditary or developmental. In another study, mandibular central incisors

dominated the list compared to premolars and it was noted more in females[12]. Missing third molars were not considered in the study sample. Treatment generally requires a multidisciplinary approach including orthodontic correction, or prosthetic replacement with a removable or fixed appliance ,endodontic correction is not much needed Age of the patient, number of missing teeth, carious teeth, and condition of supporting tissues, occlusion and interocclusal space are the important factors determining treatment planning.[13]

Microdontia and its Management

Microdontia is a condition in which teeth appear smaller than normal. In the generalized form, all teeth are involved. In the localized form, only a few teeth are involved[14]The most common teeth affected are the upper lateral incisors and third molars. The affected teeth may be of normal or abnormal morphology.There are 3 types of microdontiaA. True generalized microdontia, B.Relative generalized microdontia, and C. Microdontia involving a single tooth. Teeth commonly affected are maxillary lateral incisors and third molars[15]. When lateral incisors are affected, there is a reduction in mesiodistal diameter and convergence towards the incisal edge and this is referred to as peg shaped incisors. The condition is largely of genetic origin. Treatment mainly requires root canal treatment followed by prosthodontic intervention as the teeth are smaller in size they are useful in preparing crowns and using the teeth as abutments.[16]

Macrodontia and its Management

Typically, only a few teeth are larger than normal. Macrodontia is a very rare anomaly mostly involving the second premolar and it is believed to be a variation of obscure genetic origin .Diffuse true macrodontia is observed in pituitary gigantism and pineal hyperplasia. It has also been reported that this condition can be associated with short stature, mental retardation, minor skeletal anomalies and craniofacial dysmorphism[17].Teeth with macrodontia can undergo conservative esthetic reconstruction using a minimally invasive technique. In the case presented, the correct diagnosis and detailed planning, followed by the use of composite resin, allowed a satisfactory result, with the recovery of the self-esteem of a young patient.[18]

Dens Invaginatus and its endodontic Management

This presents clinically as pit or fissure on the lingual surfaces of anterior teeth. The classical radiographic appearance of coronal DI is as a pear-shaped invagination of enamel and dentine with a narrow constriction at the opening on the surface of the tooth [19]. The infolding of the enamel lining is more radiopaque than the surrounding tooth structure aiding easy identification. The crown is almost always malformed if the coronal invagination is extensive

Oehlers et al grouped coronal DI into three types according to radiographic appearance:

1. Enamel lined invaginations confined to the crown of the tooth;
2. Extending towards the root but not crossing the cemento-enamel junction (CEJ);
3. Penetrating the surface of the root and 'bursting' apically or laterally to produce a second foramen in the root.[20].

The majority of cases are located in maxilla and in lateral incisors. Following the maxillary lateral incisors, in decreasing order, the central incisors, premolars, canines and molars are generally affected. DI involving mandibular teeth is rare[21]. There was a higher prevalence in male patients. The possibility of the pulp being affected without a clinically detectable lesion as a result of tortuous lingual anatomy makes DI clinically significant since the enamel is thin and close to the pulp, and so there can be easy involvement[22].Pulp sensitivity testing has to be performed if radiographically apical periodontium is unremarkable in clinically suspicious teeth. If the tooth is vital then it should be restored to prevent access of the DI to the oral environment. Steffen et al have stated that if no entrance to the invagination can be detected and there are no signs of pulp pathology, no treatment is required other than fissure sealing or a minimally invasive filling. Awareness of this anomaly when present is essential especially in a case of pulpitis in the absence of any history of trauma or clinical evidence of caries or restorations [23]. DI with pulpal involvement is usually managed by conventional endodontic treatment or special endodontic techniques capable of inducing an apexification if the condition necessitates [24]. Surgical treatment should be considered in cases of endodontic failure and in teeth which cannot be treated non-surgically due to anatomical problems or failure to gain access to all parts of the root canal[25].

Talon Cusp and its Endodontic Management

Talon cusp is composed of normal enamel and dentin containing varying extensions of pulp tissue. It may connect with the incisal edge to produce a T-form or, if more cervical, a Y-shaped crown contour. It is also known by other names such as interstitial cusp, tuberculated premolar, evaginatedodontoma, occlusal enamel pearl, occlusal anomalous tubercle or supernumerary cusp [26]

Hattabetalclassified anomalous cusps into three types based on the degree of cusp formation and extension:

1. Talon: A morphologically well-delineated additional cusp that prominently projects from the palatal surface of a primary or permanent anterior tooth and extends at least half the distance from the CEJ to the incisal edge.
2. Semi talon: An additional cusp of 1 mm or more, but extending less than half the distance from the CEJ to the incisal edge. It may blend with the palatal surface or stand away from the rest of the crown.
3. Trace talon: An enlarged or prominent cingula in any of its variants (i.e. conical, bifid or tubercle-like) originating from the cervical third of the root.[27]

Its prevalence ranges from less than 1% to 8% of the with a higher frequency in males than females. The anomaly has a greater predilection for the maxilla, and maxillary lateral incisors are commonly affected in the permanent dentition followed by central incisors and canines. In the present study, this anomaly accounted for 4.28% of dental anomalies and the semi-talon form was observed.[28]

Juan et al have emphasized that early diagnosis and management of talon cusp is important to prevent complications such as occlusal interference, compromised esthetics, caries and periapical pathologies, and periodontal problems. Prevention of accidental cusp fracture and attrition has also been stressed.[29]

The treatment of talon cusp involves careful clinical judgment and review of whether the cusp contains or is devoid of a pulp horn.[30] Earlier reports, based on radio graphic examination,

stated that removal of the cusp would inevitably lead to pulp exposure that would require endodontic treatment.However, radiographic tracing of the pulpal configuration inside the talon cusp has inherent difficulties because the cusp is superimposed over the affected tooth crown. Similarly, histological examination of extracted talon teeth failed to show the presence of a pulp horn in the talon cusp. [31]

Dens Evaginatus and it Endodontic Management

This is a relatively rare dental anomaly and primarily affects the premolars but can also occur on molars, canines, and incisors [32].Dens evaginatus is a condition affecting predominantly mandibular premolars and leading frequently to pulp necrosis because of occlusal trauma. When the tooth was nonvital at the time of diagnosis, apexification procedures using calcium hydroxide were successful some cases. Diagnosis of the condition before the tooth reached full occlusion (six teeth) allowed conservative management with preservation of pulp vitality, by prevention of traumatic occlusion. The dens evaginatus was ground down in small increments to avoid pulp exposure and promote deposition of secondary dentin[33].The early diagnosis of dens evaginatus before occlusal trauma can occur should permit protection of the pulp and preservation of tooth vitality.[34].

Taurodontism and its Treatment

The pulp chamber will be widened apico-occlusally and thus, the furcations are positioned added apically than normal with bull like tooth appereance. The prevalence of taurodontism is variable, depending on the altered alternation and groups studied. It is lower than 1 in modem man. Several research accept appear in which taurodontism appears as a allotment of assorted syndromes. Ackerman and assembly believed that tooth basis analysis is primarily bent genetically but that it may be environmentally modified. In both the patients discussed above, systemic disturbances or malformations could not be articular and appropriately advised to be of non syndromec taurodontism.[35]

The teeth most frequently affected are the molars, although it can be occasionally seen in premolar and incisors and are mostly diagnosed by radiographic study. Endodontic treatment in

taurodont teeth has been described as complex and difficult.Durr et al suggested that the morphology could hamper the location of the orifices, thus creating difficulty in instrumentation and obturation[36]. The number of root canals varied in each case. Since the pulpal chamber was huge in both the cases, mechanical debridement and shaping was achieved with circumferential filing using "K" files of standard ISO size and taper. Sodium hypochlorite irrigation was limited to the initial use as the apical foramina were wide open and as a precautionary measure to avoid a hypochlorite accident. In the first case custom made gutta-percha (roll-cone technique) was used, as the main pulp chamber was huge and large wide apical foramina were present. This technique allows good apical control and adapts well to the canal configuration. Thermo plasticized gutta-percha was used in the second case as distinct apical stops were present and not like the previous case where the use of it could have caused an apical extrusion.

The remaining dentin thickness of these roots is less, leading to chances of root fracture, which is very high in such cases. Hence it was decided to reinforce the root canal walls, by using light curing composite resin. Intra radicular rehabilitation with light cured composite resin using clear light transmitting post was therefore used.[37]Layered adhesion technique was used as it allows incremental composite build up inside the root canal. Aco responding size fibre reinforced resin post was used in the post space left by the light transmitting post and a monoblock effect was created which has the advantage of good stress distribution.

Fusion and Gemination and its Management

These anomalies are also referred to as double teeth, formed as result of total or partial union in dentin and possibly their pulps. They are known to occur in both deciduous and permanent dentitions.Fusion may be partial or complete and may present with two independent root canals or less often, a single root and one or two pulp chambers. As a result, the tooth may be of normal size or larger than normal. Fusion of central incisors and canines is more frequent than that of lateral incisors and canines. These anomalies are also referred to as double teeth, formed as result of total or partial union in dentin and possibly their pulps. They are known to occur in both deciduous and permanent dentitions.Fusion may be partial or complete and may present with two independent root canals or less often, a single root and one or two pulp chambers. As a result, the

tooth may be of normal size or larger than normal. Fusion of central incisors and canines is more frequent than that of lateral incisors and canines.[38]

Gemination is an incomplete division of one tooth germ, resulting in the formation of two partially or completely separated crowns formed on a single root. It is more frequent in the anterior teeth, but can also affect molars and bicuspids. It has a prevalence of 0.5% and 0.1% in deciduous and permanent dentitions, respectively. In this review, the evidence collated that fusion accounted for 4.85%, and gemination constituted 0.28% (only one patient) of all of the dental anomalies. Fusion was observed to occur unilaterally in accordance with other studies. Mandibular teeth were affected more than maxillary. Fusion can be suspected when the number of teeth in the arch is found to be reduced and/or two roots are seen radiographically.

Twinning will appear similar clinically and are larger than normal teeth, but by definition fusion must involve dentin. Gemination can differentiated from fusion by the presence of a full compliment of teeth and an incompletely divided tooth.Twinning of teeth may adversely affect esthetics, and may lead to dental crowding and difficulty in eruption of adjacent teeth. Treatment consists of managing asymmetry, either by extirpation of the unwanted dental portion in conjunction with root canal therapy, or restoration of the exposed area. Orthodontic intervention completes the treatment plan[38].

Root- canal treatment of fused or geminated teeth has been described by various authors (Tagger 1975, Libfeld 1986, Wong 1991). A literature review failed to reveal treatment of a trifid crown permanent maxillary first premolar. Although more than one separate root- canal lends support to the diagnosis of fusion, the diagnosis of gemination was based on the clinical examination and finding that three of the canals joined to form a common main canal. The formation of this tooth within the normal complement of teeth and the similar mirror- image effect of the three crowns supports this diagnosis. Gemination occurs because of a partial division of a single tooth bud through invagination, resulting in completely or incompletely separated crowns (Pindborg 1970). In this case, the aetiology of this abnormal tooth development is unknown. Consultation with the family members and the referring dentist revealed no hereditary or causal link.

The tooth exhibited percussion and thermal sensitivity in addition to pain on palpation, symptoms indicative of an irreversibly inflamed pulp with extension of inflammatory changes to the periapex. As the tooth was caries- free and no history of trauma was reported, it is likely that the unusual anatomy lead to the irreversible condition of the tooth and the patients symptoms. Though not detected clinically, enamel deficiencies may be present in the developmental grooves between the three crowns. This would allow bacteria to gain access to the pulp chamber in a similar manner to that which occurs in dens invaginatus.

Management of the case required careful consideration of the possible morphological aberrations. Clinical and radiographic evaluation indicated that access into each of the crowns was necessary. The complexities of the root- canal systems could then be addressed during treatment. This case illustrates that, despite the unusual morphology and the lack of a comparative case in the literature, the use of sound endodontic principles resulted in successful treatment.[38]

Accessory Roots and their Management

These are commonly known to occur in mandibular canines, premolars and molars (often in 3rd molars). There are no reported studies on the prevalence or occurrence of accessory roots in different populations except for individual case reports. Accessory roots were noted in mandibular premolars and 1st molars with higher numbers in males and comprising 2% of the total anomalies [39]. This abnormality is a definite hindrance for successful endodontic treatment leading to perforations and also poses difficulty in extractions. The radiographic signs of accessory roots include double periodontal spaces on one side of the root, periodontal space crossing roots and abrupt diminution of the root canal spaces. From a clinical standpoint, radiographs or other imaging resources provide clinicians with the most appropriate method to detect variations in both root and canal anatomy. However, only by correct clinical examination and interpretation of these images can the clinician detect variations and be aware of them before and during endodontic procedures.

Dilacerations and its Endodontic Management

These are thought to arise secondary to trauma during tooth formation, altering the angle between the tooth germ and the portion of the tooth already developed.Occasionally, the bend is created by pressure from adjacent cysts, tumors or odontogenic hamartoma. Frequently, the affected teeth are the maxillary incisors followed by the mandible anteriors. In the present study, dilacerations of the roots comprised 22.5% of the anomalie.A frequent error that may occur during endodontic procedure in dilacerated root is the failure to maintain root canal curvature, resulting in ledge formation, apical transportation, zipping, perforation.To avoid these mishaps, the basic principles of endodontic therapy must be followed, that is good preoperative radiograph, straight line access to apical foramen, pre-curving the endodontic hand instrument, recapitulation, thorough irrigation and use of flexible to reach the apical foramen; enough tooth structure was removed to get the straight line access to apical foramen, giving the access cavity a cloverleaf appearance. This modifed outline form of access cavity is known as shamrock preparation which allows the endodontic instrument unrestrained in the severely curved canals. In dilacerated teeth it is often diffcult to explore and negotiate the canal to its apical foramen; hence the use of scout fle is recommended in these kind of cases.[40]

Conclusion

The present reeview attempts to evaluate the frequency of occurrence of various developmental dental anomalies in a non-syndromic global population. It was noted that anomalies were more frequent in male patients than in females. Hyperdontia, root dilaceration, peg shaped laterals (microdontia), and hypodontia were more frequent compared to other anomalies of size and shape.Developmental anomalies of teeth are clinically evident abnormalities. They may be the cause of various dental problems. Careful observation and appropriate investigations are required to diagnose the condition and institute appropriate treatment.

Ethano-Medicine in Dentistry

Subhasri Raman [1] , Madhulaxmi M [2]

Graduate Student [1],Reader [2], Department of Oral and Maxillofacial Surgery

Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstract

Herbal medicine has been used in dentistry for several years especially in countries like India and China. The photochemical properties of these herbs can provide an excellent alternative for synthetic antibiotics and have shown promising results as preventive and therapeutic medicine in oral care. Many people take herbal medicines nowadays for their health care in different national healthcare setups. Herbal extracts have been profoundly been used in dentistry for reducing inflammation, as antimicrobial plaque agents, for preventing release of histamine and as antiseptics, antioxidants, antimicrobials, antifungals, antibacterials, antivirals and analgesics. They aid in healing and are effective in controlling microbial plaque in gingivitis and periodontitis, thereby improving immunity.The main aim of this review is to study the biological activities of clove, neem and tulsi along with the importance of such traditional herbs in our daily life.

Key Words: Clove, Herbal, Remedies, Neem, Tulsi.

Introduction

Herbs are one of remedial agents which God has created for afflicted humans. Herbal extracts have been used in traditional medicine for several thousand and are staging a comeback and herbal 'renaissance' is happening all over the globe. The herbal products, today, symbolize safety, in contrast to the synthetics that are regarded as unsafe to humans and the environment. The knowledge on medicinal plants has been accumulated in the course of many centuries, based on different medicinal systems such as Ayurveda, Unani and Siddha. In India, it has been reported that traditional healers use 2,500 plant species and that 100 species of plants serve as regular sources of medicine. During the last few decades, there has been an increasing interest in the study of medicinal plants and their traditional use in different parts of the world [1, 2].

According to the World Health Organization (WHO), as many as 80% of the world's people depend on traditional medicine (herbal) for their primary healthcare needs. The development of indigenous medicines and the use of medicinal plants carry considerable economic benefits in the treatment of various diseases [3]. In the developed countries, 25% of the medical drugs are based on herbs and their derivatives [4].

Since tooth brushing is the most basic process in oral care, indigenous people all over the world use natural tooth brushes which are made from herbal healing plants. These brushes made from primitive twig actually work quite well and they provide natural-bristle which can be disposed with healing ingredients which have already been incorporated right in the plants. Herbalist, Lesley Tierra had mentioned in her, 'The Herbs of Life' (1992), volatile oils present in this twig can stimulate blood circulation and tannins can tighten and cleanse gum tissue and thereby maintain the gums healthy. Bay, eucalyptus, oak, fir and juniper, all work well for this'.

The Natural Dentist Healthy Gums Daily Oral Rinse (The Natural Dentist, Medford, Mass.) which was formerly named, Herbal Mouth and Gum Therapy, has been shown to have beneficial effects in the oral environment, such as reduction of gingival bleeding and gingivitis and inhibition of the growth of aerobic, micro-aerophilic and anaerobic bacteria [5]. This mouth rinse contains several naturally occurring, anti-inflammatory agents such as aloe vera and calendula and antimicrobial agents such as Golden Seal and grapefruit seeds. It was opined that when it was applied specifically against the broad spectrum of oral bacteria which are responsible for

gingivitis, plaque and periodontal disease, this herbal mouth rinse could prove beneficial for maintaining oral health [6].

The use of herbal remedies has assumed a global dimension, which has culminated in their being used in the treatment of various ailments in both developed as well as developing countries. Although today, only a few of these many herbs have been approved for their commendable medicinal properties, a large majority of naturally occurring herbs are only considered as food supplements, because of the lack of a randomized controlled clinical trials.. Herbal medicines are believed to be benign and to not cause severe toxicity. This, coupled with lower costs as compared to those of conventional medications, is the major attraction of these treatments. Despite the general belief, use of herbal medicines can cause severe toxicity and even death[7].

The use of herbal medicines continues to expand rapidly across the world. Many people take herbal medicines or herbal products now for their health care in different national healthcare settings. Herbal extracts have been used in dentistry for reducing inflammation, as antimicrobial plaque agents, for preventing release of histamine and as antiseptics, antioxidants, antimicrobials, antifungals, antibacterials, antivirals and analgesics. They also aid in healing and are effective in controlling microbial plaque in gingivitis and periodontitis and thereby improving immunity.

Ethnomedicine is a sub-field of ethnobotany or medical anthropology that deals with the study of traditional medicines: Not only those that have relevant written sources (traditional Chinese medicine, Ayurveda), but especially whose knowledge and practices have been orally transmitted over the centuries [8]. The current manuscript highlights various usage of clove, neem and tulsi related to oral health and suggests their derivatives in conventional dental practices.

Clove

Syzygiumaromaticum or clove an age old-spice has been used as traditional herbal medicine in Asia and Middle East Countries. Clove serves as a promisinganti-inflammatoryanti-fungal and anti-microbial, immune modulator, anti-carcinogenic and anti-mutagenic [9]. Cloves grow in hot tropical climates like the islands of Indonesia, having its native from Indonesia. The name

derives from French clou, a nailas the bud vaguely resemble small irregular nails in shape [10]. They are evergreen plants and reach a height of approximately thirty feet high. The leaves of the clove have a typical leathery textured and are usually covered with many tiny depressions along the entire length. The part of the clove that is used is the flower buds of the clove. The aromatic oils of the clove have a stimulant and irritant effect commonly encountered complaint by applicant. Cloves can bring about rise in blood pressure and body temperature [11].Cloves are the pink flowering bud of Eugenia aromatic an evergreen tree, which once dried until brown are used for medicinal and spicing purposes on a routine basis. Indigenous to the Moluccas spice islands of Indonesia, cloves also grow in India, the West Indies, Tanzania, Sri Lanka, Brazil and Madagascar [12]. Their strong aromatic flavor and powerful phenolic compounds have been the prime reason for their prominent usage for over hundreds of years as a nutritional spice for food and a remedy for health conditions. Arabic traders brought in clove buds to Europe in the fourth century A.D following which cloves became popular as a medicinal flower due to its brilliant ability to preserve food and mask poorly kept food in the seventh and eighth century A.D [13, 14].

Therapeutical Importance of Cloves

Germicidal property of clove has been exclusively used in dental care for relieving tooth ache, mouth ulcers and sore gums. Gargling with diluted clove oil can help in relieving sore throat. The aromatic efficiency of clove aids to control of halitosis [12]. Clove oil acts as an expectorant clears the respiratory tract treating many conditions like colds, bronchitis, sinus conditions and asthma [11]. Clove has a chemo- preventive role in lung and skin cancers [15, 16]. Antimutagenic property of clove was attributed to Phenylpropanoids which were isolated from the buds of cloves. These isolated products suppressed the expression of the gene. The suppressive compounds were localized in ethyl acetate extract portion of the processed clove [17].

Clove isolation has identified two anti-platelet components, eugenol and acetyl eugenol. They inhibited arachidonate, adrenaline- and collagen-induced platelet aggregation. Their inhibitory effect was reversible. These components behaved anti aggregatory based on two actions namely: (i) inhibition of formation platelet thromboxane and (ii) increased formation of 12-lipoxygenase products. It was observed eugenol and acetyl eugenol on being used in combination indicated

inhibition of platelet aggregation induced by arachidonate, adrenaline and collagen [18].Clove oil can be considered as an alternative to fishanesthetic[19].

A study was made on the effect of the cloves extract on the Cronobactersakazakii biofilm. C. sakazakii formed biofilm in the reconstituted milk after 24 hours incubation and the feeding tubes were used as the surfaces for the growth of C. sakazakii biofilm. The antimicrobial properties of clove extract were determined by comparing the thickness of biofilm on the feeding tubes before and after treatment with the clove extract. Increasing the concentration of the clove extract gave more effective result to inhibit the growth of C. sakazakii biofilm. Theresults proved that the clove extract had antimicrobial properties and can hence be used as disinfectant and solved biofilm problems in food industry [20].Specific components of cinnamon and cloves have been discovered to be efficient against mold growth and maturation till the stage of toxin production.The effects on Aspergillus parasiticus was studied using yeast extract sucrose broth being the substrate. It inhibited mold growth and toxin production. Levels of the eugenol above 200 ppm completely inhibited mold growth, or permitted only a small amount of growth [21]. Antioxidant property of spices is applied for preservation of lipids. Selected spices extracts (water and alcohol 1:1) were investigated on enzymatic lipid peroxidation. Water and alcoholic extract (1:1) of spices namely garlic, ginger, onion, mint, cloves, cinnamon and pepper on examination indicated dose-dependent inhibition of oxidation of fatty acid, linoleic acid in presence of soybean lipoxygenase. Clove exhibited highest inhibition and onion showed least. On a decreasing order the inhibitions were highest starting from cloves, cinnamon, pepper, ginger, garlic, mint and onion [22].

Home Remedies of Clove

Aromatherapy has been incorporated as a home remedy for respiratory conditions. A pomander can be hung at various places for a long standing continuous aroma therapy at home. The aroma from a hot tea with clove can also be inhaled to relieve cold [23]. Cloves can be used to remove offensive smells rather than using aerosols or other artificial air fresheners.An atomizer consisting of clove oil and water can be used. A clove pomander is another way. After the pomander has lost its effectiveness, the cloves still havemore aromas to share, which can then be crushed and used in potpourri. Cloves have excellent use in spicy potpourri. Sameatomizer can be used to freshen the air and if sprayed lightly on exposed skin it can be considered as an

effective mosquito repellent.The aromaalone from cloves will deter flies whetherit is in a potpourri an air freshener or apomander. Drops of clove oil will killants instantly. Clove oil along with cinnamon oil can kill ants [24].

Neem

Neem has been extensively used in Ayurveda, Unani and Homoeopathic medicine and has become a wonder tree of modern medicine [25]. It has been used traditionally for the treatment of inflammation, infections, fever, skin diseases and dental problems.

It is effective in several epidermal dysfunctions such as acne, psoriasis, eczema. Neem leaves have been reported to also possess antihyperglycemic, immunomodulatory, anti-inflammatory, antimalarial, antioxidant, antiviral, Antimutagenicandanti carcinogenic properties. Neem also exhibits antibacterial, antifungal, hepatoprotective, anti-ulcer, anti-fertility and anti-nociceptive activity [26].

Neem twigs are used as oral deodorant, toothache reliever and for cleaning of teeth. Neem bark possesses antibacterial and deodorant activity. The phytochemical constituents present in neem are nimbidin, nimbin, nimbolide, Azadirachtin, gallic acid, epicatechin, catechin, and margolone [27]. All these exhibit potent antibacterial activity. The chief active constituent of neem is azadirachtin, which is an effective antimicrobial agent. Neem has also been traditionally used as a skin moisturiser [28].

Azadirachtaindica is an evergreen tree having potential medicinal values. It has been found to be active against many dreadful disorders like hepatitis, viral infections, malaria and cancer. It is also effective against periodontal pathogens, and oral acidogenic bacteria responsible for dental caries and dental plaque. Nimbidin, a major active principle isolated from seed kernels of A. indicaexhibits several biological actions. From nimbidin other active constituents like nimbin, nimbinin, nimbidinin, nimbolide and nimbidicacid have been isolated which are responsible for its biological activities [27].

Antibacterial Activity

Neem is a natural antibacterial agent. Various scientific studies have revealed its antibacterial activity. The antimicrobial effects of Neem have been reported against S. mutans and S. faecalis [29]. Ethanolic extract of Neem leaves and sticks and bark exhibited significant antibacterial activity [30]. Dried chewing sticks of Neem showed maximum antibacterial activity against S. mutans compared to other dental caries-causing organisms, S. salivarius, S. mitis, and S. sanguis [31].

Anti-Candidial Activity

Ethanolic and aqueous extract of Neem leaf showed significant anti-candidial effect against C. albicans. A clinical study demonstrated the effects of the leaf aqueous extract from Azadirachtaindica(Neem) on adhesion, cell surface hydrophobicity and biofilm formation, which may affect the colonization by Candida albicans. The results suggest that Neem leaves have a potential anti-adhesive effect on the sample studied in vitro [32].

Anti-Cariogenic Activity

Mango and Neem extract showed antimicrobial activity against S. mutans, S. salivarius, S. sanguis and S. mitis. A combination of chewing sticks is found to be beneficial in eradicating the dental caries-causing organism [33]. Chloroform extract of Neem leaf inhibited Streptococcus mutans and Streptococcus salivarius also provides an aid for treating dental caries[34]. Acetone extract from the bark ofNeem is bactericidal against S. sobrinus hence indicates its anti-cariogenic activity. Antimicrobial activity of commercially available Himalaya herbal dental cream containing neem and fluoride-containing cheerio gel toothpaste has been assessed in school children. The study reported both the toothpastes showed a good antimicrobial effect on caries producing salivary streptococcus mutans. [35].

Anti-Plaque Activity

Neem oil shows significant antibacterial activity and has been suggested for use in treating dental plaque. Mucoadhesive dental gel containing Azadirachtaindica is found to be beneficial in

reducing the plaque index and salivary bacterial count comparatively better than chlorhexidine gluconate mouthwash [36].

Efficacy on Acidogenic Oral Bacteria on Fixed Orthodontic Appliance Wearing Patients

The primary acid-tolerant bacteria associated with dental plaque are Streptococcus mutans, Streptococcus oralis, Streptococcus sobrinus, Lactobacillus acidophilus, Streptococcus salivarius, Streptococcus mitis, Streptococcus sangui, Streptococcus intermedius, and Streptococcus anginosus that are seen around orthodontic appliances are one of the main complaints of the patients. It has been seen exclusively that orthodontic appliance often leads to compromised oral hygiene maintenance and plaque retention.

Ethanolic leaf extract of Azadirachtaindica has shown significant antibacterial activity against certain oral bacteria causing dental plaque in fixed orthodontic appliance patients. A study on orthodontic appliance wearers evaluated the anti-plaque activity of the extract against S. mutans, S. sanguis, and S. mitis. The extract did not inhibit L. acidophilus when tested [37].

Efficacy against Periodontal Pathogens

Brushing with Neem toothpaste after every meal and using a mouthwash with Neem extract is recommended treatment for preventing gingivitis. In a study, Neem-based mouth rinse was given to patients for assessing anti-plaque and anti-gingivitis activity. The findings conclude that Neem mouth rinse is as effective as chlorhexidine in reducing periodontal indices. Neem stick is found to be effective as a toothbrush in reducing dental plaque and gingival inflammation [38].

Studies indicate that leaf extract of A. indica-based mouth rinse is highly efficacious and that it may be used as an alternative therapy in the treatment of periodontal disease. Gingivitis has been prevented or even reversed with regular use of Neem toothpaste and mouthwash. Shefali sharma conducted a study on Soluneem (a water-soluble formulation from the Neem seed kernel from Shefali sharma conducted a study on Soluneem (a water-soluble formulation from the Neem seed

kernel from AzadirachtaIndica containing Azadirachtin) as an antimicrobial agent and the effective concentration of Soluneem required to inhibit periodontopathic bacteria and to compare it with a known antiplaque agent chlorhexidine (0.2%) in vitro. Study revealed that soluneem extract did not show activity against the organisms (Bacteroidsfragilis, B. distatonics, Prevotellacorporis, Prevotellamelagingogenica, Pepto streptococcus species) tested.

Also Botelho et al., and Behl et al., in their experiments and trials concluded that Azadirachtaindica is highly efficacious in the treatment of periodontal disease thus exhibiting its biocompatibility with human periodontal fibroblast [39].

Neem as Root Canal Irrigant

Sodium hypochlorite has been used as root canal irrigant for decades; it causes potential weakening of the tooth structure by decreasing the hardness and structural integrity of the dentin within the root canal. To overcome this

disadvantage herbal drugs are used effectively to inhibit E. faecalis that causes root canal failure in patients undergoing endodontic treatment.

Aqueous and ethanolic extract of Neem leaf inhibits S. mutans and E. faecaliswhich cause root canal failure in endodontic procedure. Its antioxidant and antimicrobial properties makes it a potential agent for root canal irrigation as an alternative to sodium hypochlorite [40]. Literature suggested that the Neem(Azadirachtaindica) leaf extract has significant antimicrobial effect against E. faecalis derived from infected root canal samples. The extract was found to be efficacious compared with 2% sodium hypochlorite.

Neem for Dental Care

Various parts of the Neem tree possess astringent and antiseptic activity. Leaf extracts have been widely used in both traditional and conventional times to manufacture toothpaste and mouthwash in the oral care dentistry. Its antibacterial properties due to the presence of nimbidin, Azadirachtin, and nimbinin help to remove many oral aerobic and anaerobic pathogens existing in the oral cavity.

Neem bark and leaf extract is most effectively used in preventing cavities and gum disease. Mouthwash containing Neem is a remedy for tooth decay, oral infections, prevents bleeding and sore gums. Twigs of Neem tree are used as chewing sticks by people all over India.

Tulsi

The plants are used for medicinal purpose since ancient times. The history of therapeutic use of plants is as old as 4000–5000 B.C. The Chinese were the first to use natural herbal preparations as medicines.The tulsi in sanskrit means 'incomparable or matchless'[41]. In ancient India the traditional medicine practitioners observed tulsi as greatest healing herb with high therapeutic potential. The botanical name of tulsi is 'Ocimum sanctum Linn'. In hindi it is known as 'Tulsi' and 'Holy Basil' in English. The tulsi plant is an erect softy hairy aromatic herb or under shrub of labiatae family belonging to genus 'Ocimum' and is found throughout India having high therapeutic potential.

Tulsi is known in different regions, languages and dialects of India by a variety of other names such as Tulasi, Surasah, Ajaka, Parnasa, Manjari, Haripriya and Bhutagni. Several species of tulsi has been seen worldwide. In India most commonly cultivated species is Ocimum sanctum Linn. The first type is green leaves type known as sri tulsi and second is purple leaves type known as krishna Tulsi. Other species of genus Ocimum which have high therapeutic potential and cultivated worldwide are Ocimum gratissium (Ram Tulsi), Ocimum canum (Dulal Tulsi), Ocimum basilicum (Ban Tulsi), Ocimum kilimandscharicum, Ocimum ammericanum, Ocimum camphora and Ocimum micranthum [42]. In Ayurveda tulsi has been well documented for its therapeutic potentials and described as DashemaniShwasaharni (antiasthmatic) and antikaphic drug. The leaves, stem, flower, root, seeds and even whole plant of ocimum sanctum Linn is used in traditional medicine. Tulsi is often enjoyed as a simple herbal tea and is frequently blended with other herbs and spices for various medicinal and culinary purposes. The Indian scientists and researchers have carried out several studies to find out the therapeutic potential of Ocimum sanctum Linn.

Chemical Constituents of Tulsi

Eugenol & Essential Oils - Ocimum sanctum L. (Tulsi) and Ocimum basilicum (Ban Tulsi) are cheaper sources for commercial extraction of eugenol. The aerial parts (leaves, flowers & stem)

of tulsi contain essential oils with good percentage of eugenol. The leaves of ocimum sanctum L. are chief source of essential oils followed by the inflorescence and stem however flowers contain more essential oils than leaves in ocimum basilicum. The roots and fruits of these plants are almost completely devoid of any essential oil. The essential oil extracted from the tulsi leaves by steam distillation largely contains eugenol.

The other important constituents of the essential oil are carvacrol, methyl eugenol, caryophyllene. To develop eugenol-rich ocimum variety scientists of Regional Research Laboratory (RRL), Jammu have developed a hybrid strain of ocimum gratissimum using recurrent selection (FCA) technique of breeding and named it as Clocimum. This Clocimum variety contains 60–65% eugenol. Another heterotic F1 strain of ocimum has been developed by Regional Research Laboratory (RRL) and named as Clocimum-3c.

This is an improved eugenol-rich ocimum variety containing 90–95% eugenol. 2. Carracrol and tetpene&Sesquiterpene b caryophylline 3. Linalool 4.Polyphenol rosmarinic acid 5.Vitamin A, C, Zinc & Iron [43].

Therapeutic Uses of Tulsi in Dentistry

Tulsi is generally considered as an Elixir of Life. Traditionally tulsi has been employed in hundreds of different formulations for the treatment of a wide range of disorders involving mouth and throat, lungs, heart, blood, liver, kidney, and the digestive, metabolic, reproductive and nervous systems [44]. The different part of tulsi like leaves, roots, flowers and stems have charismatic therapeutic potential. Tulsi has been used as expectorant, analgesic, anticancer, antiasthmatic, antiemetic, diaphoretic, antidiabetic, antifertility, hepatoprotective, hypotensive, hyolipidimic and antistress agent. As tulsi is a very effective in treatment of various medical disorders, It is also a very promising herb in management of oral diseases and dentistry. Tulsi leaves are quite effective in treating common oral infections. The tulsi leaves contains strong antibacterials like carracrol and tetpene&sesquiterpene b caryophylline.

The antibacterials present in tulsi leaves are approved by FDA as food additive. Ocimum sanctum leaves contain 0.7% volatile oil comprising about 71% eugenol and 20% methyl eugenol. Due to significant amount of eugenol (1-hydroxyl-2 methoxy-4 allyl benzene) tulsi is a strong COX-2 inhibitor. This antianalgesic property of tulsi is utilized in treatment of dental and mucosal pain[45].

The powdered tulsi leaves mixed with mustard oil can be used as toothpaste for tooth brushing. The powdered tulsi leaves used to encounter halitosis and maintaining good oral health. Massage with tulsi powder has reported to be highly effective in many gingival and periodontal diseases.The tulsi extract has high antimicrobial activity against streptococcus mutans.The streptococcus mutans has been reported to be key microorganism causing dental caries. In an in vitro study it was found that 4% concentration of tulsi extract has highest antimicrobial activity. The Tulsi also possesses a great antifungal activity. In a study conducted by Khan Ait was concluded that linalool and eugenol which are present in essential oil extracted from tulsi are effective against two strains of candida (C. albicans and Candida tropicalis) but linalool is more effective than eugenol against candidasis. [46].

The tulsi have property of immunomodulation. It also acts on skin and hemopoeitic tissues. So the tulsi can be used in treatment of oral lichen planus. However further studies are needed to evaluate efficacy of tulsi in treatment of oral lichen planus.Tulsi can also be used as antioxidant therapy in both leukoplakia and oral submucous fibrosis. The polyphenol rosmarnic acid is a strong antioxidant present in tulsi. So it can be used in treatment of all other oral precancerous lesions and condition. Due to immunomodulating property, the ocimum sanctum can be used in treatment of pemphigus. The tulsi causes healing of sores and blisters. More studies are needed to evaluate the potential use of immunomodulatory effect of tulsi in immunologically mediated mucosal disorders like pemphigus. The ocimum sanctum is a potent antiulcerogenic and have ulcer healing properties. Ocimum sanctum in dose of 100mg/kg was found to be effective against ulcers. [47]

The antiulcer effect of ocimum sanctum is reported to be due to cytoprotective effect rather than anti-secretory activity. Tulsi is effective in both oral ulcers and peptic ulcer. The tulsi is a rich source of vitamin A, Vitamin C, zinc and iron. It is also a rich source of chlorophyll and other polynutrients. So it can be used as dietary supplements in oral diseases arising due to deficiency of these nutrients. [48]

Conclusion

This review on the dental aspects of various herbal extract with their chemical constituents and biological activities helps in increasing their applications in dentistry. This information may give a bird's eye view for the dentist, and consequently this database might play a major role in future

research in the field of dentistry. The active principles of plants should be incorporated into modern oral health-care practices and dentists should be encouraged to use natural remedies in various oral health treatments.

Abstract

3D printing is atechnology in which many different materials are used to create a three dimensional model. It has the capacity to change the future of dental model production, due to the beneficial models it can create. The objective of this review is to explore the various advancementsin 3D printing that maypositively affect several aspects in dentistry. 3D printing is a revolutionary technology that has the potential to positively affect the work of dentalpractitioners, while improving the lives of others.

***Key words** : 3- dimensional , imaging, printing, technology, dentist*

Introduction

3Dprinting was previously most associated with science fictionThistechnology is now becoming an application within many industries such as manufacturing and medicine. Initially it was very expensive. As more research is being developed, 3D printing is rapidly becoming an affordabletechnology. It was originally based on ink jet principles which has the ability to print with many materials[1]. During its usage, a CAD file is processed through a specialisedsoftware and cut into a series of 2D layers. The printer then produces the object layer by layer with a supplemental support from a water soluble material[2].This reviewis focused on the applications of 3D printing in dentistry.Patients will no longer have to suffer through outdated techniques. A scan will capture the patient's mouth. This will be processed and a 3D printer will produce a replica of the mouth[3]. These major advancements are possible due to 3D printing.

History of 3-D Printing

Printing methods are constantly improved to keep up with the society. Themovable type in print technology was introduced by Johannes Gutenberg in 1400's. The rotary printing press was developed and in early 1900's lithography and letterpress machines were the dominant[4].In 1895, X-rays were discovered by W. C. Roentgen. This opened a new era in medicine and dentistry. Thirty-six years later, standardised methods for the producing cephalometric radiographs were introduced to the dental professionals by Broadbent and Hofrath simultaneously and independently, [5] and thus it remained comparatively unaltered until a few years back. Broadbent emphasised the importance of the position and the distance arrangements to produce distortionfree radiographs while taking the lateral and posteroanterior cephalometric radiographs [6]Therewere several disadvantages of 2-dimensional cephalometry as a scientific method. The fact that the conventional head filmreduces 3D objects to 2-dimensional view was the first and the most important reason. When 3D objects were displayed in a 2-dimension, the structures weredisplaceded as vertical and horizontal proportions to their distance from the film [7, 8].Secondly, cephalometric analyses were based on an excellent superimposition of the left and right sides at mid-sagittal plane. But such a superimposition was rarely observed because facial symmetry was infrequent. Third reason was that the manual data collection and processing in cephalometric analysis had been shown to have low correctness and precision [9].Finally, major errors in the cephalometric measurements were associated with uncertainties in locating anatomical

landmarks due to the deficiency of the well-defined outlines, hard edges, and shadows as well as the patient position [10].

In spite of these limitations, lots of cephalometric analyses had been developed to help in the diagnoses of skeletal and dental malocclusions and alsodent facial deformities [11,12].The quantitative errors associated with thetraditional 2D cephalometry had been substantial enough to make orthodontic diagnoses and treatment planning [13-17].

After the introduction of 3D imaging, dentists have had a great opportunity to evaluate anatomic structures 3-dimensionally in dental practice. Several investigators organised and conducted 3D imaging researches, and Singh and Savara [18]reported the first 3D analysis about the growth changes in maxilla. Computer softwares also helped to collect and analyse 3D coordinates directly from the digital cephalometric images, so that tracing manually and digitisingusingmouse on screen were abandoned [19,20].

3D imaging technique had been improved to use in different areas of medical sciences. Being improved from old photogrammetric techniques, stereophotogrammetry had been introduced so as to provide a more extensive and accurate assessmentof the captured objects. Using one or more convergingtypes of views, a 3D model could be constructed and monitored from any perspectiveand measured from any of the directions. In 1944, Thalmann-Degan recorded the facial differences after dental, more specifically, orthodontic treatment. This was the earliest clinical report about stereophotogrammetry [21].Computerisedstereo photometry has come into the market, parallel to the computer developments and has provided faster,and more comprehensive and correct taking of constructing sequences [22].

The first CT scanning device was developed around 40 years back. After a short duration of time, a stack of CT sectional images was used to obtain a3D information. At the beginning of 1980s, dentists used 3D imaging in craniofacial deformities [23]. For dento skeletal surgical needs, first simulation software was introduced in 1986. Then, the principles and the applications of 3D CT- and MRI-based imaging in dentistry were published. A specific discipline was established on 3D imaging, which dealt with different types of imaging, manipulation, and analysis of multi dimensional medical structures [24].

In 1960’s laser printing and 20 years later ink jet was brought. This technology sprays droplets of ink onto a substrate forming an image, known as 3D printing.The 3-D printing

was introduced by 3D systems in 1987. It was introduced as an additional print process which uses stereolithography for building models and prototypes. Later, 3D printing was developed and patented by the Massachusetts Institute of Technology in 1993 [25].There are several different types of 3D printing that includes Stereo lithography, Fused deposition modeling, Selective laser sintering, Traditional 3D printing, polyjet, and polyjet matrix[26]. Today,several methods of printing are used that follow traditional methods with improved capacities that produce high quality prints in a fast and efficient manner. 3D printing now with its advanced technology and versatility,can be applied to many fields[27]. This process has tremendous potential as it is valued by many industries.

Process of 3-D Printing

The 3-D print process consists of printing and post processing of the 3-D object being created. Printing with this new technique uses an additive rapid prototyping process, that is, it is based on inkjet technology. Similar to an inkjet printer that prints on a substrate with ink, 3-D printing uses this technology as a method to “jet” a binder material in the form of droplets. These droplets then conjoin with powder particles, which is deposited in layers, to create a substance[28]. In this process the powder material acts as the substrate and can be wet or dry. The liquid binder acts as an ink[29]. When printing, the goal is to distribute each layer as smooth and evenly as possible tocreate a consistent and accurate shape of the desired model. As mentioned, 3-D printing uses the principles of stereolithography to print a 3-D model layer by layer. These layers have been sliced by computer algorithms from a Computer Aided Design (CAD) file. The importantelementsinvolved in the three dimensional (3-D) printing of any object include the formulation of powder, binder material, printing of ink, and post processing which all contribute to the final formulated models[30].

Applications of 3-D Printing in Dentistry

3D printing was slow, inefficient andinconsistent process in the beginning. But today, the speed and accuracy of 3D printing are the main reasons that it is getting implemented into the fields of dentistry[31].Traditional practises were extremely uncomfortable and time consuming for patients. Time was lost waiting for moulding material to set and harden[32]. Although there wereimprovementsinthis process, it was still slow. One problemwhile using traditional casting was to create a teeth casting andto get an impression of the soft tissues of the mouth[33]. The usage of 3D printing solves some of these problems. In the olden days when a patient went to a dentalclinic - the dental practitioners had to pour goo into patients’

mouths to take impressions[34].Now, new technology has been developed that will do a digital scan of a patient's entire teeth[35]. Once it is captured by a scanner the operator delivers it to a lab where 3Dprinters are used to create the artificial dentition. With this process, it is possible to print not only teeth but also the jaw. By having a precise 3D printed mould, it is possible to create accurate prosthesis for jaw, facial reconstruction[36].Stereolithography is known to be a useful tool in maxillofacial surgery, reconstructive surgery, orthopaedics and in paediatric operations. Using this technology, templates or prosthesis can be tested and reconstructed before the operation. These three dimensional models are helpful for preoperative planning of surgical procedures[37].

Applications in Oral and Maxillofacial Surgery

Medical modelling, one of the earliest application of 3D printing in surgery, was used to produce an anatomical study model[38]. This was made even more accessible by another technology in dentistry, the CBCT[39,40].CBCT helps provide volumetric image data to a 3D printer before surgery [41] which is used in making detailed replicas of the patient's jaws. This helps review the anatomy so that a surgical approach can be planned or practised before surgery[42-43].

Applications in Prosthodontics

It is possible to develop a precise virtual model with the help of scanners[44,45]. In prosthodontics, treatment may be planned and restorations can be designed using CAD software. It may be used to mill or print crown or bridge copings, implant abutments and bridge structures.3D printing may be used for fabricating metal structures [46] either by printing in burn out resins or waxes, or in metals or metal alloys. The benefit of printing in resin/wax is that there is much less post processing involved than in the direct 3D printing of metals. Printing in metals requires the use of more costly technologies which have their own requirements and demands. When printing implant bridge structures, 3D printing may be used along with milling/machining technologies to produce an accurate mechanical connection to the implant, combining the best attributes of printing and with little waste.

Applications in Conservative Dentistry

Dentists maysometimes need a physical model of the scanned jaw for certain procedures which is now possiblewith the help of 3D printing. It may be used for fabricating a

restoration, like adding a veneering material. Patient model data may be digitally saved, and printed only when needed, easing storage requirements [47].

Applications in Orthodontics

Imaging is one of the most important tools for orthodontists as it is used to evaluate and record the size and form of craniofacial structures. Orthodontists regularlyuse 2-dimensional (2D) static imaging techniques, but the depth of structures cannot be obtained and localised with 2D imaging. So three-dimensional (3D) imaging has been developed in the early of 1990's and has gained a crucial place in dentistry, especially in orthodontics.

In orthodontics, treatment is planned, appliances are created, and wires are bent robotically using intra oral or CBCT to capture patient data. 3D printing digitally re-aligns the patients teeth to make a series of 3D printed models[48]. An example of printing is the manufacture of 3D printed, bracket bonding splints, printed in rigid and flexible materials for precise bracket placement [49]. In 3D diagnostic imaging, a series of anatomical data is gathered using certain technological equipment, processed by a computer and later showed on a 2D monitor to present the illusion of deepness [50].

Facial soft and hard tissues, and the dentition are the three main sections, also known as the triad, in orthodontics and orthognatic surgery. This triad has an important function in the planning of orthodontic treatment. Therefore, imaging of these structures is a useful diagnostic toolfor dentists to make a treatment modality [51]. 3D imaging for orthodontic uses contain preand posttreatment evaluation of dentoskeletal and craniofacial relationship, and eventually the facial appearance and beauty, evaluating the treatment results in terms of soft andhard tissues. 3D dental, facial, and skeletal images for making diagnostic decisions and treatment planning are the other benefits of three dimensional imaging in orthodontics [52].

Conclusion

3D printing technology is still in the developingstage. While it was in the marketplace since 1993, because of its limited usage, varying accuracy, high rate and slow production time, 3D printing was not an alternative to traditional modeling [53]. Presently it is used only in unique cases.Many dental practitioners are eager to implement 3D printing in their practice. This process will allow for the creation of common procedures and models to occur in a faster and

more precise manner allowing for quicker and better service to each patient[54].By reducing the time, a dental practitioner canprovide service to more patients and improvepatient satisfaction using the cutting edge technology[55]. Like other fields, using 3D technology requires a high cost. This is a major factor causing 3D printing of dental models from being a technology common in the field. In order for 3D printing to become a technologycommon withindental fields,the cost for 3D printers needs to reduce. But, due to the technology's initial stages of development, it may take a few decades before cost becomesaffordable[56]. If the cost reduces, 3D printing will become even more desirable by dentalpractitioners due to its exceptional accuracy.

Abstract

Evolution is a slow, steady and a progressive process that brings about vital changes in various organisms with time to adapt to the environmental changes they encounter. The communication between organisms or individuals primarily involves facial expressions. Therefore this review article focuses on the evolution of facial muscles of humans with other organisms such as monkeys to study their adaptive pattern with time to various stresses.

Key Words: *Chimpanzee, Evolution, Facial muscles, Human, Mammals*

Introduction

The mammalian facial muscles are innervated by the facial nerve (seventh cranial nerve) and are a subgroup of hyoid muscles; they are inserted into the freely movable skin and produce facial expressions [1]. They are responsible for generating facial expressions during interactions and also play a role in various activities such as feeding, chemo sensation, hearing and speech. It is observed that the facial muscles attach via a subcutaneous musculoaponuerotic sheath unlike the vertebral muscles that attach via tendons.

The facial muscle of various organisms was studied using a new method used by Burrows and colleagues known as the 'face mask' technique wherein the superficial facial musculature, skin and fascia are removed from the skull. It is suggested that this method helps to preserve the facial musculature more effectively than the traditional method used earlier.

On comparing the facial muscles of humans with that of other organisms it is observed that modern humans possess varied facial and laryngeal muscles that are absent in majority of the other mammalian taxa [2]. Various dissections have proven distinct similarities between humans and chimpanzees in accordance to facial muscles[3].

The *Panthera tigris* facial muscles show certain similarities as well as differences when compared with human facial muscles [4] .It was also observed that many muscles that were absent in chimpanzees were present variably in humans [5][6]. Various studies prove the hypothesis that social and environmental variables have a great influence on the evolution of facial musculature in hylobatids, which is closely related to chimpanzees [7].

Humanvs*Panthera tigris*

Tigers occupy a wide range of habitats from mountain slopes to mangrove swamps and tropical rainforests [4], in particular, not much is known about the muscles of head and neck in tigers. Recent studies have helped us realize the various similarities and differences in facial muscles with comparison to that of humans. In tigers the masseter is divided into a ventral bundle, a superficial bundle and a deep bundle. However, a ventral bundle is not present as a distinct structure in humans [4][8].

According to a study conducted by Saban in the year 1968, the pars suprazygomatica of the temporalis is often present in the Carnivora also including domestic cats, and in

other mammals such as rodents and some primates but not in modern humans; this structure is effectively well developed in our serval and tiger, being similar to that reported in *Puma* by Schumacher (1961)[8][9][10].

The body of the temporalis into a deep, posterior bundle and an anterior, superficial bundle, this is a feature commonly found in most groups of carnivorans and other mammals, being often present in modern humans [8][9]. However, the broad attachment of the latter bundle onto a broad area of the orbital part of the frontal bone lying just posteriorly to the orbit, found in our serval and tiger, is a feature less commonly found within mammals and are not present in mammals [8][11].

The intermandibularis anterior is usually not present as a distinct muscle and the digastricus anterior is connected to the digastricus posterior by a tendinous intersection and not by a true tendon as seen in a few mammals that also modern humans [12].

A controversy about the presence or absence of a pterygoideus lateralis in carnivorans has been there for a long time wherein some authors defended that the muscle is usually completely missing in these mammals, others defended that it is present but displays a peculiar fusion with the pterygoideus medialis, and still others proposed that the two muscles are actually completely separable [8]. However, further studies by authors suggested that pterygoideus lateralis and the pterygoideus medialis are effectively deeply blended, and that the former muscle is undivided, as found in other felids such as domestic cats i.e. it is not differentiated into distinct superior and inferior heads as is often the case in various mammalian taxa, including modern humans [9].

When the hyoid muscles were studied, it was observed that the muscle originates from the skull, jugulohyoideus and/or proximal part of the hyoid apparatus and attaches onto a strong aponeurosis that indirectly connects it to the hyoid apparatus in case of tigers. But the modern humans the stylohyoideus originates from the styloid process and splits around the intermediate digastric tendon to insert onto the body of the hyoid bone [8][13].

Examples of other differences between modern humans and our serval and tiger include the following wherein the former the sphincter colli profundus,

interscutularis, levator anguli oculi medialis, retractor anguli oculi lateralis, platysma cervicale, and sphincter colli superficialis are usually not present, and the depressor supercilii, depressor septi nasi, depressor labii inferioris and depressor anguli oris are usually present, as distinct muscles [9].

It is also observed that similar to domestic cats, tigers have more facial muscle structures associated with the mobility of the auricular region than that of modern humans and most other primates, which usually only have three mainly undivided facial muscles connecting the ear to the skull, i.e., the auricularis anterior, auricularis superior and auricularis posterior [14].

Further when the branchial muscles are studied it is seen that the muscles stylopharyngeus and ceratohyoideus are seen in tigers whereas modern humans are observed to lack ceratohyoideus but possess stylopharyngeous[9].

Some other differences between tigers and humans are that the levator depressor septi nasi, depressor supercilli, depressor labii inferioris and depressor angulioris are usually present, as distinct muscles and also sphincter colli profundus, interscutularis, levator anguli oculi medialis, retractor anguli oculi lateralis, platysma cervicale, and sphincter colli superficialis are usually not present [9].

Humans vs other Therian mammals

It is observed that humans have a lesser number of mandibular muscles when compared to that of other mammals such as tree shrews, rats and fewer muscles than that of reptiles such as lizards [2]. Recent studies have rendered the cause for this phenomenon by establishing three reasons. Firstly, most of the evolutionary splitting that occurred during transitions has led to the origin of amniotes and mammals [2]. Further, some muscles that were present in our ancestors were lost during various stages of evolution [2]. Lastly, some of the muscles found in the sarcopteygian taxa are peculiar and features of that taxa[2]. It is observed that the number of laryngeal and facial muscles found in other mammals is much lesser than those seen in modern humans [2]. Excluding the extrinsic muscles in the ears, the modern humans have 24 facial muscles where as researchers have observed only 20 in case of rodents such as

rats and tree shrews such as *Tupaia* have 21. In case of laryngeal muscles, there are 4 muscles in *Tupaia* and rats whereas 6 muscles are present in human beings.
Many studies also suggest that the number of true branchial muscles found in modern humans are smaller than that found in most other mammals. Actually, in the case of these muscles if there is a 'trend' at the time of the evolutionary transitions that led to the origin of primates and subsequently to modern humans, then it is to reduce, and not increase, the total number of muscles. It is observed that the monotremes like platypus have 8 muscles; followed by rodents like rats with 7, Tree shrews like Tupaia have 6 muscles and the modern humans are observed to have 3 muscles [9].

In case of pharyngeal muscles, there is an increase in the number of muscles when evolutionary change that lead to therian mammals occurred but no increase was observed when an evolutionary transition lead to the existence of modern humans. It is observed that the platypus generally have 3 muscles, rodents like rats have 8 muscles, colugos have 8 muscles tree shrews such as Tupaia have 7 muscles while modern humans have 7 muscles [9].

On studying the hypobranchial muscles that does not include the intrinsic muscles of the tongue, it is observed that the modern humans have more muscles than the other taxa. For example, rodents like rats have 8 muscles, colugos have seven muscles, and tree shrews like Tupaia have 8 muscles while the modern humans have nine muscles [9].

Many studies were also conducted on the facial and laryngeal muscles, which shoed that humans possessed more muscles that any other taxa. Modern humans usually have 24 facial muscles without including the extrinsic muscles of the ear, monotremes like the platypus have 10 muscles, rodents such as the rats have 20, colugos have 19 muscles while the three shrew such as the Tupaia have 21 muscles [9].

Examples of facial muscles present in modern humans and which are lacking in most other mammals are the risorius, depressor supercilii, levator labii superioris alaeque nasi, depressor septi nasi, depressor labii inferioris and depressor anguli oris [15][16][17].

Human vs. Chimpanzee

Chimpanzees (*Pan troglodytes*) have an elaborate repertoire of facial signals, but little

is known about their facial expression (i.e. mimetic) musculature underlying these movements, especially when compared with some other catarrhines. It is observe that there are minimal anatomical differences between chimpanzees and humans.

One of the major differences found in a study conducted by Burrows on *P. troglodytes* and humans was the firm fusion and, often, intimate infiltration of the superficial fascia into some of the muscles, such as the deep head of the occipitalis muscle, the zygomaticus major muscle, and the depressors anguli oris and labii inferioris muscles. It was observed that in these muscles the superficial fascia was firmly blended with the muscle fascicles and slowed progression of the dissection. However, the relationship between the superficial fascia and musculature in human facesshowed the superficial fascia typically lies only loosely on top of the muscle [18].

Similar to modern humans, the facial expression musculature in *P. troglodytes* are observed to be thickest and most numerous in the area of the oral cavity. These organisms live inloose dispersed communities where the large group may frequently break out into numerous small groups to interact with other groups and then reunite with their old community [19]. Males are generally dominant with a clear dominance hierarchy and frequent territorial disputes [20]. In these intricate social settings, a variety of vocal, chemical and visual communication modes are employed to send information on social intentions, emotional states, and various aspects of an individual such as age, sex and reproductive status [21]. *P. troglodytes*are reported to use a number of facial expressions to communicate various intentions [20]. The silent bared-teeth and relaxed open-mouth displays are the most common facial expressions seen in social contexts which involve the lips, and very few displays are noted to include movements of the orbital region, scalp or pinna. The preponderance of musculature associated with the oral region may indeed reflect these behavioralobservations for *P. troglodytes* [22].

Human vs. Rhesus macaque

The rhesus macaque is one of the least-studied primates on the basis of facial musculature and this is considered as an essential exercise as these monkeys are used as models for understanding various human diseasesand abnormal emotional and social behaviors such as Parkinson’s disease, autism, AIDS and schizophrenia.

[24].

Macaques as a genus [Cercopithecoidea: Cercopithecidae] exhibit a number of social styles. They have the ‘tolerant’ species such as stump-tailed macaques (*M. arctoides*), Tonkean macaques (*M. tonkeana*) and lion-tailed macaques (*M. silenus*). These species are characterized by relatively relaxed and egalitarian dominance styles with tolerance toward subordinates, low levels of aggression, and high levels of reconciliation and affiliation. Social interactions between and among conspecifics tend to be bidirectional. They also have another extreme that are the ‘despotic’ species such as crab-eating macaques (*M. fascicularis*), pig-tailed macaques (*M. nemestrina*) and rhesus macaques (*M. mulatta*). A rigid dominance hierarchy characterizes these species with little tolerance toward subordinates, unidirectional and high levels of severe aggression and low levels of reconciliation in females. Any affiliations tend to be kin-based [24].

Muscle	**Rhesus Macaque**	**Chimpanzee**	**Humans**
Platysma	P	P	P

In both tolerant and despotic species individual must communicate with one another and this is done mainly via vocalizations and visual displays such as facial expressions. Both the vocal and facial display repertoires of some macaque species are relativelywellunderstood, especially in rhesusmacaques (*M. mulatta*). Facial displays and vocalizations in this species conveyinformationrelatedto the rank of the sender, individual identity, reproductivestatus and emotional state/intent of the signaler [17]. As in humans and chimpanzees, rhesusmacaquesintegrate vocalizations and facial displays and mayusethesemodes both individually and simultaneously.

Occipitalis	P	P	P
Frontalis	P	P	P
Superior auricularis	P	P	P
Posterior auricularis	P	P	P
Anterior auricularis	P/V	P	P
Inferior auricularis	P/V	A	A
Orbitoauricularis	P	A	A
Tragicus	P	P	P
Antitragicus	P	A	P/V
Orbicularisocculi	P	P	P
Orbicularis oris	P	P	P
Mentalis	P	P	P
Levator labii superioris	P	P	P
Depressor septi	P/V	P	P/V
Corrugatorsupercillii	P	P	P
Depressorsupercillii	P/V	P	P
Procerus	P	P	P
Levator labii superioris alaeque nasi	P/V	P	P
Caninus	P	P	P
Depressor anguli oris	P	P/V	P
Zygomaticus major	P	P	P
Zygomaticus minor	P/V	P	P/V
Risorius	A	P	P
Depressor labii inferiori	P	P	P

The most common facial display of *M. mulatta*that is well understood and documented extensively are the 'silent-bared teeth' and the 'relaxed open-mouth' . These displays have been cited as homologues to human laughter and smiling, respectively. Thus, an increased understanding of rhesus macaque facial display behaviors may inform our understanding of the evolution of human communication and social behavior [17]. The following table shows a comparison of muscles between Rhesus Macaque, Chimpanzee and modern humans [Table 1] [24][25].

Table 1: This table compares the facial musculature of Rhesus macaque with Chimpanzee and modern humans.

Key - P- Present; A- Absent; P/V- Muscle was variably present

Thus the results of various studies suggest that the rhesus macaque share a more similar facial musculature with chimpanzees and modern humans than it was previously considered.

Human vs. Hylobatids

Hylobatids, which include the gibbons and siamangs [Primates: Hominoidea: Hylobatidae), are small, arboreal, and territorial lesser apes found throughout the

evergreen forests of southeast Asia including Indonesia, Eastern India, Vietnam, Laos, Cambodia, and Southern China Together with humans and the great apes (chimpanzees, bonobos, gorillas, and orangutans) they comprise the superfamily Hominoidea [27]. During evolution of the hominoids, it is said that the hylobatids were the first to branch off, over 17 million years ago [28][29].

A total of 22 muscles were present when not counting the buccinatorius muscle, which is not typically involved in facial expressions. The depressor septi nasi muscle was found to be variable in two of the four specimens of hylobatids. The hylobatids, the phylogenetically distant rhesus macaque, and the more closely related chimpanzee have roughly the same number of mimetic muscles. One of the primary differences among these three taxa is that the risorius muscle is only consistently present in chimpanzees (as it is in humans and gorillas), and not in hylobatids and rhesus macaques [26].

Complexity of facial musculature in hylobatids in various studies conducted by Burrows suggested them to be mixed. In the musculature of the external ear, hylobatids had poor separation of these muscles from the occipitalis, frontalis, and auriculo-orbitilis muscles by way of intersecting fascial connections. This series of connections would, by definition, decrease complexity of the musculature and possibly the ability to move the external ear independently from the scalp. The procerus muscle was poorly separated from the frontalis muscle in hylobatids, which may decrease the ability to move the skin over the external nose separately from the skin of the superciliary region. In addition, the zygomaticus major and depressor labii inferioris muscles were exceptionally gracile relative to both the chimpanzee and rhesus macaque [26]. This study conducted by Burrows also mentioned a double-headed zygomaticus minor muscle in hylobatids, which may be viewed as having great complexity relative to the chimpanzee and rhesus macaque [26].

Micro anatomically, the hylobatids when examined the upper lip was found with approximately even distributions of connective tissue and muscle fibers, unlike the chimpanzee and rhesus macaque, which had relatively densely packed muscle fibers and very little connective tissue [30]. The present study also suggests that there was no indication of separate pars marginalis and pars peripheralis layers in the hylobatid orbicularis oris muscle, a contrast with the chimpanzee [30].

Thus the hypothesis derived from these studies suggests that environmental and social variables are influential in the evolution of morphology and complexity of facial musculature in hylobatids. Duetting (and loud vocalizations in general) is one of the key characteristics defining hylobatids and seems to be the primary mechanism of communicating with con- specifics outside of the small ‘‘family’’ group .It is suggested that the process and evolutionary mechanisms of hylobatid duetting would possibly have decreased selection pressure on development of facial displays and facial musculature complexity relative to both the distantly related rhesus macaque and the closely related chimpanzee [26].

Conclusion

Thus from the above review we can conclude the various evolutionary changes in the facial musculature of human beings when compared to various other mammalians and non-mammalians. This data will help in various experimental studies done to study the progression of a disease in humans with the other mammals or non-mammals as models. The researcher must be well aware of the similarities and variations present between humans and the model organisms to make a proper hypothesis and analyze the condition tested effectively[31][32]. It is also evident from this review that more evaluation of the facial musculature of various organisms is necessary as multiple investigations help in identifying many variants of the musculature that were not mentioned in the earlier studies. These studies also help us predict the future evolutionary pattern of the humans which the influence of social and environmental changes they are subjected to. This data helps various comparative anatomists in analyzing the musculature of the different evolutionary species of the same and various taxa.

Failures In Composite Restoration – A Review

Mohammed Ahad [1], Remmiya Mary Varghese[2]

Graduate student [1] ,Senior lecturer [2],Department of Orthodontics

Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstract

Aim: To review common causes of failure in composite restoration

Background: In recent years, the demand of tooth colored restorative material and its advantages has led to a rapid increase in the use of resins. The steady growth of interest in 'cosmetic' treatments led to increase in use of composite fillingswhich are naturally an attractive alternative to silver amalgam restorations, particularly in clinical situations where the restorations would otherwise be visible. This review is based on the failures of composite restoration and problems faced by dentist and patient. Some of the major problems are shrinkage of resins, post operative sensitive, fracture of restoration, wear, inadequate finishing and polishing etc

Reason: This review paper will be useful in understanding the problems related to the failures of composite restoration

Key words:*Composite, failures, shrinkage, wear, review*

Introduction

As per McLean, the main endeavour to create plastic restorative materials was uncovered in the Allied Field Information Technical Report No. 1185, distributed in 1947. A cold cured acrylic resin for use in restorative dentistry was produced in Germany [1]. The self-cured, unfilled acrylic materials could be put specifically into the prepared tooth. The polymer and monomer were combined and embedded into the pit where it polymerized. In any case, these amine-containing resins were not shading steady and turned dull on introduction to sunlight. They additionally had issues of over the excessive working time to set initially (1.5 minutes), poor compressive quality, low grating protection, low modulus of versatility, high water absorption and a polymerization shrinkage of 7% by volume. Their high coefficient of thermal expansion additionallypredis-postured they to miniaturized scale spillage and the issues related with microleakage [2]. In 1958, the main composite resin material, P-Cadwrit, was made accessible in Germany. In 1959, Bowen recorded his first patent in the U.S.A. on the renowned Bis-GMA resin. The upsides of composite resins in light of Bis-GMA resin over an acrylic resin include: bring down polymerization shrinkage, non-volatile, bring down exothermic properties, more prominent compressive quality and less lethal to the pulp [3]. Knight et al built up the urethane dimethacrylates in 1973. A resin was made for use in composite dental materials along these lines which have points of interest of higher molecular weight, lower viscosity and less in vivo stain-in with use than Bis-GMA (l) resins.

According to Lutz et al [4], filled remedial resin consists of three-dimensional mixes of at least two synthetically extraordinary materials with a surface interfacial stage. The 3 stages are: the matrix stage, the surface interfacial stage, and the dispersed stage. Every resin "should likewise incorporate a quickening agent initiator framework to start and finish polymerization. The artificially cured composites by and large utilize an amine-peroxide framework, though the light-cured resin utilizes a diketone-amine framework which is actuated by the extraordinary blue light. What's more, pigments and opaquers are added to control translucency and shade. The resin framework is a dimethacrylate oligomer such Bis-GMA or urethane-diacrylate. The surface interfacial stage comprises of either a bipolar coupling specialist to tie the natural resin grid to the inorganic fillers, or copolymeric of homopolymeric bond between the natural Fine-Particle measure Composite Resins network and fractional organic filler. The level of interfacial bond and compound solidness is basic for fruitful clinical utilization of any composite resin [5]. Lutz et al [4] grouped the dispersed stage in view of the three noteworthy classes of filler particles utilized. Conventional macrofillers comprise of quartz, glass, borosilicate, and ground or smashed ceramic. The measurement of macrofillers particles go from 0.1 to 100A.055/lm. Microfillers are normally pyrogenic silica which is indistinct, finely light cured. Contrasted with the large particle composite dispersed particles of around 0.04A.05.5/lm in estimate. The resins, they furnish a smoother restorative surface with micro filler-based complexes are generally one of three less surface degeneration, better shading solidness and higher writes: [1] fragmented prepolymerized particles of I to 200A.05 5/lm in estimate, [2] circular prepolymerized particles of 20 to 30A.055/lm in width, and [3] agglomerated microfillercomplexes of I to 25A.055/lm in diameter. Self-cured resins arefavourable where compos-degeneration at the

filler-matrix interface would in any case composite resin should be put in regions of the mouth where light can't reach adequately [2] Be that as it may, the visible light-cured resins have numerous preferences, including: control over the working time, quick completing of resins and cases of rebuilding and control over the profundity of cure. Since no mixing is required, it implies simpler dealing with and insignificant porosity, the real advantage is that the rebuilding will be significantly more shading stable contrasted with self cured resins. Subsequently, most of the composite resins now accessible are light-cured resins [2, 6].

Dental composites consist of a polymerizable resin matrix, particle fillers, reinforcing glass and silane coupling agents [7]. These glass particle/resin matrix composites have good aesthetic properties and strength, making them the most widely used materials for restorations of anterior teeth [8]. Development of modern dental composite restorative materials started in the late 1950s and early 1960s, when Bowen [9] began experiments to reinforce epoxy resins with filler particles.

Since 1990, numerous classifications of resins composites have been presented. Composite Resins have been utilized for almost 50 years and quite a long time upgrades have been made with respect to their composition and their properties. The majority of them contrasted chiefly in the specific filler matrix utilized, e.g. conventional/customary, little molecule composites, matrix (smaller scale hybrid, monohybrid, submicron cross breed and monohybrid) [10]. The consolidation of the filler in the composite material has improved the mechanical properties of the composite, for example, compressive and rigidity, surface hardness or resistance to surface space[11].On the other hand, posterior composite restorations have been shown to produce higher failure rates due to secondary caries [12,13].

Light Curing

Every composite requires a specific measure of energy (joules) for finish curing. This may differ by the manufacturer, by the sort of composite material, and the shade of the composite. It is a component of the energy of the curing light (mW/cm2) and the measure of time that the light is conveyed. Tragically, the measure of delivered energy can fluctuate because of the improper position of the light tip, movement of the light tip amid curing, separation of the light tip from the resin, shade and type of the resin material, state of the light curing unit, or thickness of the resin . Indeed, even the most capable curing light won't cure a composite on the off chance that it isn't legitimately set. Because the best layer of the composite is hard, that does not imply that the composite is cured at the base.[14]

All in all, insufficient consideration is given to legitimate position of the curing light or the state of the light. The best possible measure of irradiance is controlled by the manufacturer and the shade of the composite. Deficient or inadequate curing unfavorably influences the resin physical properties, lessens the bond quality to the tooth, diminishes the biocompatibility of the restoration, increments negligible wear and breakdown, and increments bacterial colonization of the restoration [15] A few reviews have demonstrated that numerous QTH (quartz-tungsten-halogen) curing lights in dental workplaces don't convey enough light energy to totally cure composites[16].

Size and Location of Restoration

The position of the tooth in the curve and the size of the cavity have been appeared to be a factor in the accomplishment of a restoration. One investigation found the risk of failure in the molar region to be twice as high with respect to premolars, [17] while another examination put the failure rate in bring down molars as three times that of the upper premolars. [18] Multi-surfaced restoration efforts are additionally more inclined to failure than single surface restoration. An investigation figured that for each surface added to the restoration, a 40% expansion in the failure rate resulted. [17]

Polymerisation shrinkage

Every single composite resin contract amid polymerization, such withdrawal is named polymerization shrinkage. Polymerization shrinkage of composite resin is critical as a result of its impact on cavosurface edges. It causes partition between a composite resin mass and the adjacent tooth structure. Negligible adjustment of a composite resin rebuilding is reliant on a few variables including: polymerization shrinkage, hygroscopic properties, holding between restorative material and the cavity walls. Coefficient of thermal expansion of the material, and the Finishing methods [19-22]

It has been exhibited that regardless of acid etching of enamel walls, hygroscopic expansion of composite resin, cautious completing strategies, and utilization of material with warm expanxivity like that of enamel, marginal gaps will in any case result from polymerization recoil age. Such shrinkage may cause minor gap development, or when the finish - resin bond stays in place, it might bring about damage inside the composite resins as micro cracks which may cause untimely disappointment of the restoration [23]. The shrinkage properties of composite resins are subject to both the physical components of the materials and how the materials are cured and dealt with clinically. Different composite materials have been appeared to display polymerization shrinkage from around 1.5 - 5.5% by volume [19]. Late investigations report shrinkage of around 1-2% volume for posterior compositeresins contrasted with around 4-5% volume for early ordinary composites [24]. Joining of a high division of filler particles alongside a fitting creation of the monomer matrix hypothetically would give a composite resin the most minimal conceivable polymerization shrinkage. The measure of volumetric change in back composite resins when cured has been expressed as one of the principle determinants of the life span of the composite resin reclamation.

When matrix monomer convert to polymer Composite shrinks immediately upon setting (2-3% by volume) stresses are invariably generated within the material at the margins on shrinking [25]. Larger the increment of compo- site, greater the total shrinkage, this will again increases the potent- tail for stress formation [26]

Consequence of polymerisation shrinkages

i. Weak bonds can occur due to polymerisation shrinkage this causes failure of composite in bonding with the tooth structure

ii. Post-operative sensitivity [26]

iii. Marginal gap formation

iv. Ingress of bacteria and secondary caries [26]

v. The contraction forces transmitted to enamel and dentin, causing cusp flexure, fracture or crazing of enamel and fracture in composite material [27].

Appropriate Placement Technique

Numerous specialists suggest incremental arrangement of the composite in light of the abatement in the "C" factor and the resultant reduction in the shrinkage stress. [28] This has been the prescribed strategy; in any case, with the presentation of the low shrinkage stretch composite materials, mass filling has turned out to be better known. Due to their low stresses and great profundity of cure, these composites might be what have to come. Regardless of which procedure that is utilized, legitimate matrix placement is critical for the restoration achievement. A restoration that has an open contact or a gingival overhanging isn't a worthy rebuilding. Nourishment impaction from an open contact does not prompt great gingival wellbeing and an open or rough edge may prompt bacterial development and possible intermittent decay. Sectional matrix frameworks and isolating rings may lead better shapes, contacts, and marginal seal.

Proximal Box Placement

Bonding failures have been usually credited to the gingival margins of Class II composite restorations. [29] In the proximal box of most Class II restoration, there is practically zero polish at the edge for bonding. Holes at the gingival edges have been ascribed to the potential for poor bonding at this margin.[30] The disparity between etching depth and adhesive invasion prompts a substantial region of exposed collagen at the gingival margin.[31] Another variable that may meddle with the bonding in the gingival region is water content. Expanded water content prompts lessened adhesive invasion and lower monomer/polymer transformation of the adhesive at the gingival edge when contrasted with the proximal wall. [32] Sometimes, the situation of a glass ionomer as the principal layer for these deep margins might be considered due to a portion of the great characteristics of this material [33].

Water Absorption

The specialized properties of composite resin are influenced by ingestion of water, which goes about as plasticizer and pressure consumption operator, debilitating the molecule network interfaces. Confined swelling happens at the filler-lattice between confront causing deboning, which may prompt hydrolytic breakdown. Separate on the surface of composite pitches may likewise be encouraged by temperature changes and dissolvable impacts. The

higher the temperature, the more fast the water absorption [34]. The measure of water ingestion in posterior composite resins utilized today is around 0.2 - 0.6% by weight. Water retention will prompt breakdown of the composite resin with utilize.

Wear

Wear might be characterized as the undesirable expulsion of strong material from surface because of mechanical action[35]. The customary vast molecule measure composite resin contains expansive filler particles which are impressively harder than the resin network. Amid rumination, stresses are transmitted onto the rebuilding surface and especially the particles anticipating from the occlusal surface. Since the particles are harder than the resin network in which they are implanted, a great part of the pressure is transmitted through the molecule into the resin itself. Stress will think and turn out to be too much high where the submerged portion of the molecule is angulated or irregular shape as a fiddle. Such a condition has a tendency to create little breaks around the molecule, along these lines debilitating the lattice locally [36]. Another age of composite resin has hence been produced which contain filler particles of decreased sizes yet expanded filler stacking. The measure of stress around every molecule is diminished which result in a huge lessening in loss of anatomical form. In some composite resin, softer filler particles have been incorporated keeping in mind the end goal to diminish the distinction in hardness between the filler and the network. At the point when softer filler particles are utilized, the masticator stresses are in part consumed by the molecule, instead of being completely transmitted into the encompassing matrix [23]the utilization of softer filler particles in this way diminish the likely hood of creating little splits around the filler and debilitating the framework locally.

Shade Matching

Correct shading coordinating of the restoration and the tooth is an imperative part of the aesthetic restoration. Numerous things can confound making the right shade choice, for example, the lighting framework in the operatory, the way that teeth lighten when got dried out, the shade of the operatory or the patient's dress, and the experience of the individual doing the shade determination. Shade choice requires learning of material science and the physiology of shading; subsequently, it is both an art and a science requiring top to bottom knowledge, precise clinical judgment, and discernment with respect to the dentist. [37] Unfortunately, the confinements of shade guides are critical variables that compromise shade matching methodology in dentistry and add to the dissatisfaction of clinicians, specialists, and patients. [38]

Improper manipulation:

i) Acid etching

Etching time is 15-20 sec on permanent tooth whereas its 60 sec on primary tooth, as it is more amorphous & does not form the deep resin tags. Enamel require more etching time as fluoride content is more & it is impervious to etch, The end results of etching that it appears as irregular surface and frosty white owing to light refraction [25]..

ii) AcidStrength

Buonocore utilized 85% phosphoric acid first. However, later examinations said higher concentration are less effective & are more likely to denude surface, so research suggest 37% phosphoric acid is the ideal concentration [39].Care ought be taken that acid should replenish before use as it evaporates during storage.

i) Under etching

Inability to accomplish a cold surface could come about because of under etching /hypo calcified enamel [39].

ii) Over etching

Can cause an insoluble reaction product monocalcium phosphate that gets dried out which avoids additionally etching and causes feeble bonding [39].

Average time for an adult permanent is 20 sec while for newly erupted Permanent teeth is 15 secs and for deciduous teeth it's 60 – 120 sec. Washing time is about 10 sec, Insufficient washing leaves debris that interferes with the flow of resin. 60 sec washing with heavy water spray actually weak resin- enamel bond as enamel rod crushed [25,39]

Drying

Electric hot air dryers are the most ideal approach to dry an etched enamel surface. They have appeared to enhance enamel bond quality by around 29%. The least desirable is three way syringe / liquid drying [25, 39]

Type of etching material

For pits & tissues, liquid is recommended. For smooth surface etching, liquids & gels results in similar etch patterns [39].

Oil sullying of hand pieces or/Air water syringes

The oil originates from air compressors, a large portion of which are not kept up well in dental workplaces. Any of the present dentin bonding agent combined with oil defilement gives an eccentric clinical outcome and potential clinical disappointment. Expelling all oil ought to be a prompt goal. Air filters should be placed on the air lines. [40]

Isolation and placement of rubber damn

Composite can be easily contaminated by moisture Isolation is necessary during adhesion and bonding of composite resin to tooth structure. Improper isolation causes decreased bond strength & ultimately physical & mechanical properties of compo- site restoration also decreases [26]. Isolation can be done with rubber dam, gingival retraction cords etc. But the placement of rubber dam is most important procedure. For success & longevity of composite restoration Appropriate contour and contacts are important. This can be achieved by proper placement of rubber dam [41, 42]. Although dentin is a wet substance, the constituents of saliva and blood create an environment that can destroy dentin bonding. Use of rubber dam or other dry field aids are necessary to avoid salivary or blood contamination during placement of tooth adhesion materials [40].

Selection criteria

Composites are indicated in class III, IV & V lesion in anterior teeth & small to moderate class I & II cavities [11]. Failure in case selection occurs, in case with poor oral hygiene as composite resin get easily attached to a higher level of pathogenic bacteria than other restoration, which may lead to recurrent caries due to microleakage [26]

Marginal failure and fracture of restoration

Poor marginal strength is the characteristic feature of composite [43]. So margins of restoration should be away from the occlusal contact points. If margins left open there may be chances of microleakage resulting in formation of secondary caries [44]. Marginal fracture is more common than bulk fracture [10].

Microleakage

Microleakage can cause postoperative sensitivity and bacterial invasion e.g. Streptococcus mutans. Microleakage results in subsequence inflammatory changes, secondary caries & discoloration of restoration [40]. Marginal gaps are primarily results from polymerization shrinkage on setting of resins [45]. After setting, dimensional changes occurs by masticatory forces, thermal changes & water sorption of composite restoration [44]

Inadequate finishing & polishing

A proper finishing& polishing is to be done, as all rough surfaces acts as an entry for microorganisms. Sharp projections irritate & inflame gingiva so interporximal areas should be given importance. Dentinal margins can be open at dentin-restoration when dry polishing & finishing is doneusing the burs having number of flutes, lesser will be the damage [42].

Post-operative sensitivity

Post-operative sensitivity can arise if we fail to avoid the cause of shrinkage and placement of restoration. It is caused when a Gap is created between restoration & tooth surfaces [44]. Pressure changes in dentinal fluids as flexural strength of composite restoration and tooth differs which transmitted to the pulp.

Conclusion

Composite material has a high rate success of longevity when used in posterior restoration. This review has highlighted the major causes for failures of composite restoration. To enhance the accomplishment of these restorations, factors related to the patient and operator is of great importance, which indicates the need for a conservative approach toward restoration replacement and its prevention.

Abstract

Doctors experience play a major role in fabricating and designing the dentures,but the selection of dental resin is also important. Dentists are advising flexible partial dentures because they make better and stronger appliances that are comfortable and long lasting. The strong and flexible nature of the material perfectly suits the variety of natural conditions in the mouth, simplifying design and enabling the flexible nylon resin to act as a built-in stress-breaker in order to provide superior function and stress distribution in a removable partial denture. Unilateral or bilateral undercuts are frequently encountered and may complicate successful fabrication of denture prosthesis. This review is to ensure the better purpose of flexible dentures compared to conventional acrylic denture its advantages and its disadvantages.

Key Words*: Denture base, Denture resin, Valplast, Retention, Stability.*

Introduction

Loss of teeth, which may be due to trauma, dental diseases, pathology, or otherwise not only alters the psychological thought of the patients but also disturbs the esthetics, phonetics, and functional occlusion[1]. Replacement of missing teeth is highly essential in order to restore the defect and regain function as best as possible.Modern dentistry offers many options for the restoration of partially edentulous mouth, like removable partial dentures (RPD), fixed bridges and dental implants. Removable partial dentures became very popular with the introduction of acrylic polymers and chrome cobalt alloys in dentistry. Many patients choose removable partial dentures due to factors ranging from cost to physiology[2]. Dentists are advising flexible partial dentures because they make better and stronger appliances that are comfortable and long lasting. The strong and flexible nature of the material perfectly suits the variety of natural conditions in the mouth, simplifying design and enabling the flexible nylon resin to act as a built-in stress-breaker in order to provide superior function and stress distribution in a removable partial denture. Unilateral or bilateral undercuts are frequently encountered and may complicate successful fabrication of denture prosthesis[3,4]. The advancement of the nylon-inferred denture base material in the 1950s prepared for another kind of dentures. Adaptable dentures are a magnificent contrasting option to customarily utilized methyl methacrylate dentures, which give great style and solace as well as adjust to the consistent development and adaptability in incompletely edentulous patients.Adaptable fractional dentures are dental prosthesis made of thermoplastic nylon sap called polyamides utilized as a part of expert dentistry since 1954[5,6]. Dental practitioners utilize adaptable dentures to supplant at least one of your missing teeth either in the upper or lower jaw.Adaptable halfway dentures are agreeable, delightful, and a reasonable decision in this cutting edge time. It was for some time imagined that removable fractional dentures must be unbending to be powerful[7]. The development of the adaptable incomplete dentures enables the reclamation to adjust to the steady development and adaptability in the mouth. This is the fundamental reasoning behind the inventive adaptable, removable halfway denture. Flexible temporary dentures are suggested by dental specialists amid restorative scenes. After careful reproduction of the upper jaw, there is a need to oblige the patient amid the period amongst medical procedure and the creation of a last dental machine[8,9]. For this reason, an adaptable denture offers an awesome arrangement that enables the patient to recommence day by day exercises. Midline break of finish dentures has been accounted for to be the second most basic sort of crack in denture prosthesis. Adaptable denture material has been accounted

for to have restorative preferred standpoint in beating midline denture cracks. Adaptable dentures frame an astounding other option to customary hard fitting denture. [10,11]. Material being delicate and solid can be made more slender and are light in weight contrasted with customary dentures that advances better adjustment of the tongue and cheek to the denture base. These dentures retain little measures of water to make the denture all the more delicate tissue good[12]. Because of their capacity of superb mouldability, light weight to thickness proportion and high warm quality, adaptable dentures have been demonstrated as a fantastic treatment alternative for finish and halfway edentulism[13]. Be that as it may, watchful case choice and clinical judgment is required to utilize adaptable dentures in fitting circumstances keeping in mind the end goal to acquire a fruitful treatment result. The adaptability, joined with quality and lightweight, gives add up to solace and awesome looks [14].Management of these situations conventionally includes alteration of the denture prosthesis bearing area, adaptation of the denture base, careful planning of the path of insertion and the use of resilient lining material. An alternative denture prosthesis design in which optimal flange height and thickness can be achieved is by using flexible denture base material. Soft dentures are an excellent alternative to traditional hard-fitted dentures [15]. Traditionally relining dentures with a soft base increases comfort at the cost of chewing efficiency. To make up for the loss of chewing efficiency, denture wearers would use dentures adhesive which causes its own problems. A flexible material is now an option that does not trade off the ability to eat[16].

Functional Benefits of Flexible Materials

Acrylic partial dentures offer a relative ease of fabrication as compared to the metal frame. The cast partials require accurate tooth preparations for guide planes and placement of occlusal rest. Very accurate surveying is required on the diagnostic cast to help inform about the tooth preparation [17]. However, the main limitations from these materials come from a steady loss of function as the edentulous ridge undergoes a natural process of resorption and the obvious non-aesthetic visible metal clasps. The patient needs to maintain the partial dentures routinely in terms of clasp adjustment and relines, and if any of the requirements are slightly compromised, the design will fail to work as intended. Irrespective of the accuracy with which the metal partial denture is designed for its fit, this perfection is gradually lost after the partial denture is placed.Soft dentures are generally only used when traditional dentures cause discomfort to the patient that cannot be solved through relining.

Soft dentures are not the same as a soft reline for traditional dentures [18] .Soft relines use a soft putty-like substance to separate gums from the hard acrylic in dentures. Flexible dentures use a special flexible resin that prevents them from chafing the gums, allows the wearer to chew properly. It also provides a soft base that prevents the gums from being rubbed raw.Flexible dentures have got various advantages over the traditional rigid denture bases. Translucency of the material picks up underlying tissue tones, making it almost impossible to detect in the mouth [19].

Valplast

Valplast is a flexible denture base resin that is ideal for partial dentures and unilateral restorations. The resin is a biocompatible nylon thermoplastic with unique physical and aesthetic properties that provides unlimited design versatility and eliminates the concern about acrylic allergies. The Valplast Flexible Partial allows the restoration to adapt to the constant movement and flexibility in your mouth. The flexibility, combined with strength and light weight, provides total comfort and great looks[20,21].

Advantages

1. Flexible dentures have got various advantages over the traditional rigid denture bases. Translucency of the material picks up underlying tissue tones, making it almost impossible to detect in the mouth.
2. No clasping is visible on tooth surfaces (when used in manufacturing of clear clasps), improving aesthetics. The material is strong and flexible. Free movement is allowed by the overall flexibility [22].
3. Complete biocompatibility is achieved because the material is free of monomer and metal, these being the principle causes of allergic reactions in conventional denture materials. Clinicians are able to use Valplast, Duraflex, Flexite, Proflex, Lucitone, Impak where as valplast and lucitone are monomer free. Areas of the ridge that would not be possible with conventional denture and partial techniques can be accessed by these flexible dentures.
4. Patient can wear appliances that would normally not be comfortable. Flexible dentures will not cause sore spots due to negative reaction to acrylic resins and will absorb small amounts of water to make the denture more soft tissue compatible. Flexible dentures may be used as an alternate treatment plan in rehabilitating the anomalies such as ectodermal dysplasia [22].

5. Metal-free restorations and prosthesis are future of dentistry. Flexible partial is the optimal choice whenever partial is the choice of treatment or the patient prefers not to use a fixed restoration. Patients, who have used both conventional RPD and a Flexible partial, report that the later feels more natural and is more comfortable to wear [23].

6. It also provides a higher standard of function by using the flexibility of the material to balance masticatory forces over the entire supporting ridge instead of individual support points (Phoenix et al, 2004). The balanced distribution of forces can often lead to longer lasting appliances that may not require frequent relines. Following are some of the advantages of a flexible partial denture: More acceptable esthetics, since there are no metal clasps. The material has good flexibility like Titanium. Therefore, even if there is a little bit of bending, it comes back to the original shape and position [24].

7. Ease of insertion in the mouth with alveolar undercuts because of the flexibility. Even if there is slight shifting of the remaining teeth over time, the flexibility of the denture material, allows the use of prosthesis with little adjustment. There is no need of modification of the remaining teeth to receive occlusal rests as for the metal clasps. In cases of undercut due to tilted teeth, flexibility of the material makes it possible to insert the prosthesis over the angulated teeth[22].

8. The denture can be heated up in hot water for about a minute and can easily be adjusted and inserted in the undercut area. A real boon for patients with compromised oral conditions. Opens up scope to address the needs of such patients with ease[24]

Ultra-light and thin.

The material thickness may shift from 0,6 mm to 1,8 mm so every nylon denture is five times lighter than standard dental prosthesis and much more if contrasted with metal cast partials. Adaptable dentures influence you to disregard the cumbersome inclination that made wearing fractional apparatuses so awkward previously.

Other Advantages

- Conceivably Unbreakable

The nylon base makes the prosthesis adaptable in this way, it might ingest well an inadvertent tumble to the ground amid the home oral cleanliness.

On account of its unbreakable element, a few brands, for example, Valplast offer lifetime guarantee that apply to the adaptable material as it were. At the end of the day, prosthetic

teeth (made of sap or porcelain) are not secured by the guarantee. If you don't mind make sure to deal with the dental machine with mind[23].

- Anallergic and Profoundly Biocompatible

Polyamides (otherwise called thermoplastic nylon gum) doesn't contain bisphenol (BPA) consequently it is the most biocompatible material for building dental pitches. Polyamides dentures is a substantial option for patients that experience the ill effects of sensitivities to acrylic or certain metals, for example, chromium and cobalt utilized as a part of the system of conventional fractional dentures. Nylon dentures are viewed as sans metal dental apparatuses.

- Agreeable and Fantastic feel

Adaptable partials benefits incorporate agreeable. Contaminate, they adjust to the steady development and adaptability in the mouth. Because of delicate material, they don't cause gingival bothering.

Since there are no metal catches around your common teeth, they are essentially imperceptible.

The shade of the base material mixes with the characteristic shade of the gums in your mouth. Nobody will find you're wearing an adaptable fractional denture[25].

- Stain and Smell Safe

Regardless of whether adaptable incomplete denture are more impervious to catch scent and to recolor (we should consider the pigmentation because of espresso, tea, cigarettes smoke and wine) than conventional acrylic dentures despite everything they should be legitimately cleaned and kept up as portrayed underneath

- Non-Deformable

Depicting standard fractional denture, we said that while you are not wearing it, It is smarter to place it in a glass of water or in a sodden little towel. The reason is basic, If a denture gets dry it tends to change its shape. With adaptable dentures this hazard doesn't exist since they generally have a tendency to return to their unique shape. Anyway, dental practitioners dependably counsel their patients to keep their adaptable partials hydrated utilizing legitimate fluid[23].

Disadvantages

1. Being a plastic material, it cannot be made into thin sections like metal.

2. It is likely to break if cut thin sections. Since they need to be made bulkier than cast partials, it may take longer to get used to a flexible partial denture. It does not conduct heat and cold like metal.

3. The patient may not enjoy certain food like hot soup or ice cream. Since flexible dentures utilize the gaps (because of some missing teeth) for the 'Retento-Grip Tissue-bearing Technique' (Iselin et al, 1990) for retention, the remaining teeth have to be in fairly good periodontal health[25].

4. The patients that have periodontal problem may have several teeth that are mobile due to bone loss. Therefore, the whole area keeps on flexing causing unfavorable forces that in turn result in more bone loss. The laboratory fee is a little higher.Requires more chair-side time for adjustment.

5. A Flexible denture is very hard to repair if fractured. No additions can be made onto it. In such cases, rebasing is recommended.Flexible dentures generally not used for long-term restorations and is intended only for provisional or temporary applications. Flexible dentures tend to absorb the water content and will discolor often. Metal frame partial dentures remain the" standard" for long-term restorations. When grinding this prosthesis, proper ventilation, masks, and vacuum systems should be used and the procedure is technique sensitive[9].

Conclusion

Flexible dentures were previously selected by few patients and the clinician but now a days it has become an elective treatment option.Flexible partial dentures can be a good option for the replacement of missing teeth when patient is concerned about aesthetics.The rehabilitation of orofacial structures demands the restoration of esthetic and function irrespective of the individual's dietary / parafunctional habits and structure left. They have given a option of thinking beyond complex designing of cast partial dentures. The fabrication of the optimum restoration is depending on the clinicians skills in selection of the type of the restorations which is required for the patientFlexible dentures will stand in a superior are allergic to monomer. Demand for more retentive and aesthetic treatment needs. Flexible dentures were previously selected by few patients and the clinician but now a day it has become an elective treatment option. Position in fulfilling the various patients. VALPLAST plaster is the

flexible partial denture allowing the restoration to adapt to constant movement and comfort along with great looks. VALPLAST is the most commonly used.

Saveetha University, Chennai, India

Abstract:

The aim of the study is to show the various dimensions of foramen magnum shown by the male and female population. The objective is to study the various anteroposterior , longitudinal and transverse dimensions seen among the population in the foramen magnum. Sex determination between people is most commonly identified based upon morphological shape, size and structure changes seen with them. Many craniofacial skeletal structures damaged after air accidents, mass disasters, fire, explosion makes difficult to determine the gender and the consequent identification. This identification can be done and studied based upon morphological changes in the individuals. This study makes the forensic people to estimate the gender and sex identification in simple manner. In additional to this, the article gives the review on different dimensions of foramen magnum shown by the population.

Key words : *Foramen magnum, sex, identification, males , females*

Introduction:

Personal identification is the act of establishing the identity of a person—by linking him/her to the stream of data in the information systems. It beholds a major portion in forensics and usually relies on the comparison of the known features to the unknown specimen. Identification of an individual is vital for the family not only from an emotional standpoint but is also a medicolegal requirement [1]. In living individuals, identification plays a pivotal role in cases such as property disputes, insurance claims, issuance of passports, and various other licenses, whereas after death, it becomes important to identify the deceased as in case of a murdered victim, or file closure of a person missing for a prolonged period to facilitate the rituals of body disposition following death and permission of remarriage. So, the society's duty to preserve human rights and dignity beyond life begins with identity. Hence, positive identification is required both for legal and humanitarian reasons.

Sex determination reduces the search of individuals by 50%[2] and is 98% accurate when the whole skeleton is available [3]. But finding an intact skeleton is not always likely.In such circumstances, pelvic bone possesses highest sex discriminant accuracy of 95% [4]. The skull is the second best alternative [5] and is 90% accurateto determine the sex of the decedent [4]. However, in explosions, warfare and mass disasters, human remains are often obtained in fragmented states. In such circumstances, only strong bones that greatly resist fracture are likely to be recovered intact. Forensic investigators have thus attempted to utilize them for personal identification. The base of the skull is one such bone and establishing sex discriminant value of the skull base has attracted attention. The aim of this article is to highlight the anatomical and clinical features of foramen magnum followed by its forensic role in human identification.

Foramen magnum [FM] is an important structure of the skull base. It is located inferior to the sagittal suture and surrounded by the basilar, squamous, and lateral parts of the occipital bone. Situated in the deepest part of the posterior cranial fossa and covered by a large volume of soft tissue, it is an ideal structure for sex determination. Sexual dimorphism in FM dimensions is population-specific and highly influenced by environmental, socioeconomic, and genetic factors. The foramen magnum [Latin: great hole] is a large opening in the occipital bone of the human skull. It is one of the several oval or circular openings [foramina]

in the base of the skull. The foramen magnum is found in the most inferior part of the posterior cranial fossa [6].The spinal cord, an extension of the medulla, passes through the foramen magnum as it exits the cranial cavity. Apart from the transmission of the medulla oblongata and its membranes, the foramen magnum transmits the vertebral arteries, the anterior and posterior spinal arteries, the tectorial membranes and alar ligaments. It also transmits the spinal component of the accessory nerve into the skull.

The diameter and area of the foramen magnum are greater in males than in females, hence its dimensions can be used to determine sex in the medico legal conditions, especially in the following circumstances, such as explosions, aircraft accidents and war fare injuries [7]. Foramen magnum is about 3cm wide by 3.5cm anteroposteriorly [8]. It is located midway between and on a level with mastoid processes. The foramen magnum is surrounded by different parts of the occipital bone, squamous part lies behind and above, basilar part in front and a condylar part on either sides [9]. On each side its antero-lateral margin is encroached by occipital condyles, hence the foramen magnum is narrow anteriorly. The anterior edge of the foramen magnum is slightly thickened and lies between the anterior ends of the condyles. The posterior half of the foramen magnum is thin and semicircular. Upper ends of anterior and posterior atlanto-occipital membranes are attached to the anterior and posterior margins of the foramen magnum respectively, and their lower ends are attached to the superior surface of anterior and posterior arches of the atlas respectively. The foramen magnum is a wide communication between posterior cranial fossa and the vertebral canal. The narrow anterior part of the foramen magnum has apical ligament of dens, upper fasciculus of the cruciate ligament and membrana tectoria, both are attached to the upper surface of basioccipital bone infront of the foramen magnum. Its wide posterior part contains the medulla oblongata and its meninges. In subarachnoid space spinal rami of the accessory nerve and vertebral arteries, with their sympathetic plexus, ascend into the cranium; the posterior spinal arteries descend posterolateral to the brain stem, where as anterior spinal artery descends anteromedian to the brain stem. The cerebellar tonsils may project into the foramen magnum.

Interest in the anatomy of the foramen magnum [FM] is largely interdisciplinary-made evident by numerous anatomical studies from the fields of physical anthropology, forensic anthropology, comparative anatomy, evolutionary biology, and surgery.

Development Of The Foremen Magnum :

During fetal development, the anterior and lateral aspects of the FM are formed from the basioccipital, the exoccipitals, and their respective interoccipital synchondroses anterior while the posterior boundary of the foramen is formed by the supraoccipital, the exoccipitals, and their corresponding interoccipital synchondroses posterior. The fetal growth centers do not fully ossify until approximately 10 years of age until which time both the size and shape of the FM are undergoing change. Between the 7th month in utero and birth, the rate of FM growth in its sagittal dimension is 5.4% greater than that of its transverse dimension.Between birth and 0.5 years, the opposite trend is observed – the rate of transverse growth is 7.6% faster than that of sagittal growth.Mean adult sagittal lengths are attained by 5 years of age, whereas mean transverse lengths are not attained until 10 years of age.

Landmark Of Foramen Magnum:

The opisthion is the centre on the posterior margin of the hiatus and could be a cephalometric landmark. Another landmark is that they basion situated at the centre on the anterior margin of the hiatus.

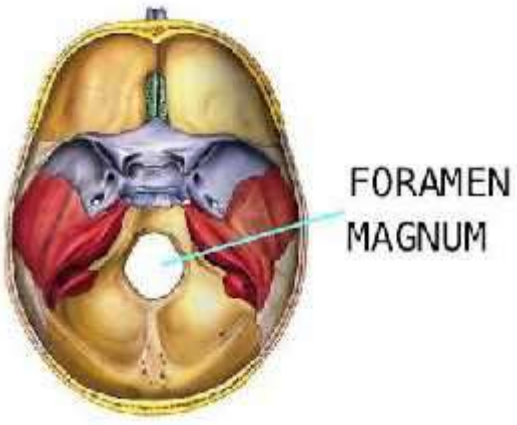

Image 1 : Showing Foramen Magnum

Relation Of Foramen Magnum:

anteriorly - basilar part of occipital bone

anterolaterally - occipital condyles, hypoglossal canal, jugular foramen
posteriorly - squamous part of occipital bone with the internal occipital crest

Contents :

medulla oblongata
meninges
spinal root of the accessory nerve
vertebral arteries
anterior and posterior spinal arteries
tectorial membrane and alar ligaments

Radiographic Features :

CT :

at the amount of the hiatus CSF is seen to surround the medulla that is reduced or absent in tonsillar hernia.

Measurements Of Foramen Magnum:

-Longitudinal diameter [LD] of the foramen magnum - It is distance between basion and opisthion.
-Transverse diameter [TD] of the foramen magnum - It is maximum distance between two lateral margins.
Measurements of the foramen magnum were taken by vernier callipers to the nearest of 0.1mm. Measurements were taken twice and average of two values was taken as final measurement. Area of the foramen magnum It is surface area of the foramen magnum calculated by the following formula [10].

AREA [A] = ¼ X p X w X h w = Width, transverse diameter h = Height, longitudinal diameter = 22/7, mathematical constant.

Morphometry And Morphologyoftheforemenmagnum :

Adult females have a reported mean sagittal FM diameter ranging from 27.1 to 36.66 mm whereas adult males have a reported mean sagittal diameter ranging from 32 to 40.0 mm [11].Adult females have a reported mean transverse diameter ranging from 25.45 to 31.34 mm,whereas adult males have a reported mean transverse diameter ranging from 26.92 to 38.0 mm [12] . Studies reporting both female and male mean sagittal and transverse diameters agree that male FM diameters are longer than those of females [13] . Aside from documenting the ratio between sagittal and transverse diameters [i.e., FM-index], the study of FM shape has been largely limited to assigning shape categories to foramina. The shape of the FM has been classified with ambiguous terminology such as “asymmetrical,” “biconvex,” “bi-pointed oval,” “bi-rounded oval,” “circular,” “dorsally convergent oval,” “egg,” “heart-like,” “heptagonal,” “hexagonal,” “irregular,” “oval,” “pentagonal,” “pear,” “polygonal,” “rhomboid,” “round,” “symmetrical,” “tetragonal,” “two semicircles,” “ventrally wide oval,” and “wide oval ” [14].

Sahoo et al. [15] reported the FM to be mostly in the shape of “two semicircles,” and furthermore, both pear- and egg-shaped more often than oval-shaped; however, similar to the Henríquez-Pino et al.'s [16] study, Sahoo et al. [15] did not identify a tetragonal category. Indeed, Aragão et al. [17] classified FM into eight categories and still noted that “in the remaining 6.36% of the FM, it was not possible to define a regular and specific form.

Knowledge of morphometric and morphologic variation of the FM in different populations has implications for a variety of scientific fields; however, the structure of the FM has not been studied among several geographically and craniofacially distinct populations.

Discussion :

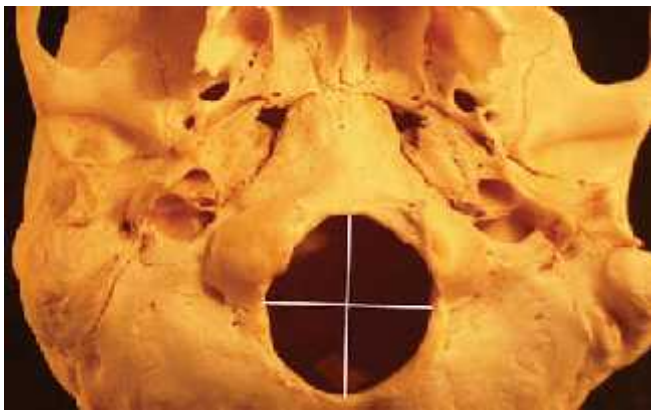
Sex determination helps to channelize the investigation by deducing the search to half the population, thus conserving both resources and the time required for identification. When the entire skeleton is present, sex determination is possible with 100% accuracy. However, in many instances human remains are likely to be obtained in fragmented states. In such situations, the pelvis has demonstrated maximum accuracy in sex determination followed by the pelvis if available with cranium, pelvis with long bones, and long bones or skull in isolation. The base of the skull, precisely the occipital bone is often recovered intact, even in cases of severe trauma due to its well-protected anatomical position and large amount of overlying soft tissue [18].

FM is a vital and prominent structure of the skull base. It has been found to exhibit differences in its dimensions between males and females. But this sexual dimorphism is population-specific, as demonstrated by studies on the populations of Iraq, Turkey, Brazil, Poland, and Nigeria. This is also seen in India in diverse geographical locations such as Uttar Pradesh, Gujarat, Chandigarh, and Madhya Pradesh. The dimensions of FM are also influenced by genetic, environmental, and social factors. Many authors have demonstrated sexual dimorphism in the South Indian population as well [19]. FM completes its growth by early childhood. It is unresponsive to secondary sexual changes, with no influence of musculature on its size and shape, making it considerably stable beyond adolescence [20].

Babu [21] found the mean LD values to be 35.68 mm in males and 32.57 mm in females; Kanchan et al. [22] reported values of 34.51 mm in males and 33.6 mm in females. The mean values of TD as reported in these studies were 28.91 mm in males and 28.19 mm in females [Babu R]; 27.36 mm in males and 26.74 mm in females [Kanchan et al.].

In CT scan images, the longitudinal diameter and area of the foramen magnum of male subjects was higher than females, whereas transverse diameter of the foramen magnum of male was not significantly higher than females. In a morphometric evaluation of the foramen magnum of normal adults by CT scan showed. In males sagittal diameter varied from 31-45mm with an average of 37.2±3.43 mm, transverse diameter varied from 27-40mm with an average of 31.6±2.99 mm and area of foramen magnum was varied from 710-1266mm2 with an average of 931.7±144.29mm2. In females the sagittal diameter was varied from 28-42mm with an average of 34.6±3.16mm transverse diameter was

varied from 28-42mm with an average of29.3±2.19mm and area of the foramen magnum was varied from 671-1006mm2 with an average of 795.0±99.32mm2.



The correlation coefficient between stature and breadth of foramen magnum shows extreme significance [p = 0.006] in the southern Chinese population, but is not statistically significant [p = 0.932] in the northern Chinese population [24].

The morphological differences between skulls of different genders are mainly determined by genetic factors rather than nutrition, hormones, or muscles [GÜNAY, 2000]. Thus, the determination of gender in human skulls is based on morphological differences, mainly on the size and strength of certain structures [ROSING, 2007], which may be characteristics of each population that are influenced by genetic, environmental, and socioeconomic factors [25] .

Conclusion:

From this review study , we noticed that males show significant value than females in the sexual dimorphism of foramen magnum dimensions. The skull base and the occipital bone are protected by a large amount of soft tissue, and the anatomical position is useful for many craniofacial skeletal structures are damaged after air accidents, mass disasters, fire, explosion, or injuries resulting from violence.

G6PD Deficiency

Benazir Hussain M[1], Sivakumar M[2]

Graduate Student[1],Senior Lecturer[2], Department of Oral and Maxillofacial Surgery

Saveetha Dental College, Saveetha Institute of Medical and Technical Science, Saveetha University, Chennai, India

Abstract

Glucose-6-phosphate dehydrogenase deficiency (G6PDD) is an inborn error of metabolism that predisposes to red blood cell breakdown.Most of the time, those who are affected have no symptoms.Following a specific trigger, symptoms such as yellowish skin, dark urine, shortness of breath, and feeling tired may develop.Complications can include anemia and newbornjaundice.Some people never have symptoms.It is an X-linked recessive disorder that results in defective glucose-6-phosphate dehydrogenase enzyme.Red blood cell breakdown may be triggered by infections, certain medication, stress, or foods such as fava beans.Depending on the specific mutation the severity of the condition may vary. Diagnosis is based on symptoms and supported by blood tests and genetic testing.A high degree of variation exists between human populations and individuals with respect to malaria incidence, parasite density and disease severity and reactions to anti-malarials. Although in some studies glucose-6-phosphate dehydrogenase deficiency (G6PDd) is associated with protection from severe malaria deficient individuals are reported to suffer from haemolytic anaemia when treated with primaquine, which is the only available drug against *Plasmodium falciparum* gametocytes and a radical cure of *Plasmodium vivax*. Further individuals with G6DPd are reported to suffer from haemolysis when treated with tafenoquine, another anti-malarial with proposed indication of treating hypnozoites of *P. vivax* and *Plasmodium ovale* .G6PDd is one of the most common human enzymopathies which is in a very high frequency in tropical and subtropical malaria endemic regions. In sub-Saharan Africa (SSA), the prevalence of G6PDd can reach up to 35% although organized reports are lacking and different allelic variants are unevenly distributed in the region. However, with progressive improvements in detection methods past G6PDd prevalence figures may need continuous revision. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common enzyme deficiency in humans, affecting 400 million people worldwide. It has a high

prevalence in persons of African, Asian, and Mediterranean descent. It is inherited as an X-linked recessive disorder. G6PD deficiency is polymorphic, with more than 300 variants. G6PD deficiency confers partial protection against malaria , which probably accounts for the persistence and high frequency of the responsible genes. This review gives a detailed description on diagnosis, clinical manifestation and treatment of g6pd deficicency.

Key Words*: g6pd deficiency, favism, jaundice,cancer, haemolytic anemia*

Introduction

The structure of enzyme G6PD monomer consists of 515 amino acid subunits with a calculated molecular weight of 59,256 daltons. The active enzyme exists as a dimer and contains tightly bound NADP. Aggregation of the inactive monomers into catalytically active dimers and higher forms requires the presence of NADP.[1] Thus, NADP appears to be bound to the enzyme both as a structural component and as one of the substrates of the reaction. The binding sites for this coenzyme have not been identified at the structural level, but examination of mutants has suggested that amino acids 386 and 387, the basic amino acids lysine and arginine, respectively, seem to bind one of the phosphates of NADP.[2] The evidence that this site is involved in the binding of NADP is as follows:

(1) all mutants that rapidly lose activity at a 10 pmol/L NADP concentration, but are reactivated at high concentrations of NADP have been shown to have mutations in this region;

(2) mutations in this region result in paradoxical electrophoretic migration of the enzyme as if it had become more positively charged, even when the amino acid change adds a negative charge, suggesting failure of binding of negatively charged NADP.

It has also been suggested, on the basis of the deduced conformation of the peptide chain of the yeast enzyme, that the NADP binding site may be elsewhere, but the data on the human enzyme seems much more compelling to me.[3] The glucose-6-phosphate binding site has been identified at amino acid by locating a lysine at this position that is reactive with pyridoxal phosphate in competition with glucose-6-phosphate.

Enzymology

G6PD catalyzes the first step in the hexose monophosphate pathway (HMP). It oxidizes glucose-6-phosphate to 6- phosphogluconolactone, reducing NADP to NADPH. The HMP is the only source of NADPH in the erythrocytes and it also serves to produce the ribose needed for synthesis of nucleotides in the salvage pathways.[4] The main function of the pathway seems to be to protect the RBC against oxidative damage. Glutathione peroxidase (GSHPx) removes peroxide from the erythrocyte. Reduced glutathione (GSH) serves as a substrate for this enzyme, and because NADPH is required for the reduction of oxidized glutathione and protein sulfhydryl groups, it is an essential factor in the chain of reactions that defends the RBC against peroxide. RBCs are a particularly rich source of catalase, but this enzyme is relatively inefficient at removing low levels of peroxide levels. Moreover, catalase has the ability to bind NADPH tightly and the inactive form, compound 11, is reactivated by NADPH. Thus, the activity of the HMP serves to remove peroxide not only through the action of GSHPx, but also by activating catalase.[5]

The long-standing controversy about which is the more important, catalase or futile. Clearly, both enzymes may play a role and serve as backup mechanisms for each other. Which is more active at any one time may depend on the particular conditions under which the measurements are being made and very likely the particular peroxide substrate that is being catabolized. The Km of G6PD for NADP is very low, roughly 2 to 4 pmol/L, and the enzyme is strongly inhibited competitively by NADPH. Thus, the NADPWNADP ratio within the RBC controls the rate of the reaction in an autoregulatory manner. In the quiescent state, the NADPWNADP ratio is very high, and G6PD is nearly completely inhibited. When NADPH is oxidized, as when oxidized glutathione is reduced in the glutathione reductase reaction, NADPH is converted to NADP and G6PD becomes active, reducing NADP to NADPH. G6PD-deficient cells are unable to respond adequately to such an oxidative stress.[6] When the susceptibility of a mutant enzyme to inhibition by NADPH is greater than normal, this compounds the metabolic difficulty of the cell.

Clinical Manifestation

A.HemolyticAnemia

Drug-Induced Hemolysis

The first and best-known morbid effect of G6PD deficiency was drug-induced hemolysis. Primaquine is but one of many drugs that shortens RBC life span in G6PD-deficient

persons.[1] The administration of such drugs is followed, after a 1- or 2-day delay, by a fall in the hemoglobin (Hb) concentration. Particles of denatured protein adherent to the RBC membrane which is Heinz bodies, appear in the early stages of drug administration and disappear as hemolysis progresses. Appearance of RBCs that have variously been designated in such “irregularly contracted RBCs,” “eccentrocytes,” “hemighosts,” “double-colored RBC,” and “cross-bonded cells” are another morphologic feature observed on the blood film.[2] The Hb of these cells is confined to one side of the erythrocyte, leaving the other part as a flat, Hb-free ghost. In this portion of the cell, the inside surface of the membrane is tightly bonded.” Often Heinz bodies are included in the flattened region, where they may bulge visibly out of the leaflet. The urine turns dark and the patient may complain of back pain when the hemolysis is severe. When G6PD deficiency is relatively mild, as in the class 3 G6PD A-, the hemolyticanemia is self-limited because only the older RBCs are destroyed and young RBCs have normal or nearnormal enzyme activity. In patients with more severe forms of enzyme deficiency such as G6PD Mediterranean, young cells are severely deficient in G6PD,I5 and as a consequence, hemolysis continues until well after the administration of drug is stopped.[3]

As a matter of fact, it is difficult to be certain in some cases, whether a cause-and-effect relationship exists between ingestion of a drug and hemolysis. The most robust data regarding the potential hemolytic effect of drugs and chemicals comes from clinical investigations with Cr-labeled erythrocytes. However, even results obtained using RBC survival studies can be misleading. Individual inherited differences in drug metabolism such as acetylator status play a significant role in determining whether a drug will be hemolytic.[4] Thus, if a recipient who efficiently catabolizes the active hemolytic metabolite of a drug is challenged, hemolysis will not be apparent, but the drug may be hemolytic in a subset of individuals who metabolize the drug less efficiently. Moreover, even when a drug does shorten RBC life span, as shown by performing sensitive studies with Crlabeled erythrocytes, the degree of hemolysis may be so modest as to be of no clinical significance. Sulfamethoxazole, a component of the commonly used combination Septraa and Bactrima, has been shown to produce shortening of the RBC life span in Asian subjects with G6PD deficiency, but no significant hemolysis could be shown when this combination was used clinically in patients with G6PD A-.[5] RBCs from subjects with severe class 2 variants such as G6PD Mediterranean may be sensitive to drugs when those with milder defects such as G6PD A- are not. The data obtained from Cr survival must be supplemented with less reliable information gained from clinical observations.

Clinical studies are confounded by the effect of intercurrent infections which may be responsible for hemolysis rather than the drug that has been administered.[6]

Favism

A clinical manifestation of G6PD deficiency closely related to drug-induced hemolysis is the hemolyticanemia induced by ingestion of the fava bean, Viciafaba. Favism, this hemolyticanemia, has been known since antiquity.[7] Indeed, the demise of Pythagoras has been attributed to unwillingness to enter a bean field, possibly because of favism, although the evidence supporting this interpretation is feeble. Patients with favism are always G6PD deficient, but not all G6PD-deficient individuals develop hemolysis when they ingest fava beans.[8] Thus, G6PD deficiency is a necessary but not sufficient cause of favism. Presumably some other factor, probably also genetic and very likely related to metabolism of the active ingredients in the beans, is involved. The vast majority of cases of favism occurs in individuals with severely deficient (class 2) variants of G6PD, but occasionally favism has been observed in a patient with G6PD. Although at times the onset of hemolysis in favism may be more explosive than occurs as a result of drug administration, in general the course of hemolysis in favism is very similar to that occurring after drug ingestion.[9]Hemolysis does not usually begin for 24 hours after ingestion of the beans and hemoglobinuria may continue for several days.

Mechanism of Hemolysis

The mechanism by which drugs and fava beans produce hemolyticanemia is not well understood. Such drugs do not lyse RBCs in vitro.[10] Instead, they appear to inflict oxidative injury on the erythrocytes and, therefore, are often designated as oxidative drugs. Because of its relatively high frequency in some areas in the Mediterranean region, the mechanism by which fava beans produce hemolysis has received special attention, with the suggestion that the pathogenesis of favism and drug-induced hemolyticanemia may be essentially the same.[11]Vicine, convice, ascorbate, and L-DOPA are abundant in fava beans and have been considered candidate toxins. The most likely offenders are vicine and convicine, &glucosides of pyrimidine compounds that are converted by glucosidases to their aglycones, vicine and isouramil, respectively. These compounds form reactive semiquinoid-free radicals and can generate active oxygen species. This results in the formation of ferrylhemoglobin, methemoglobin, and inactivation of various enzymes. The reactions that occur are complex and varied and therefore, largely unpredictable.[12]

Infection-Induced Hemolysis

Although, for historical reasons, drug-induced hemolysis has attracted the most attention, it is likely that hemolysis induced by infection may be a more common cause of clinically significant hemolysis.[13] Numerous reports attest to the importance of infection in causing hemolyticanemia. It is clear that many different types of infections may trigger hemolysis in the G6PDdeficient patient. The mechanism by which this occurs is not clear, but an imaginative suggestion has been that during phagocytosis, leukocytes damage erythrocytes in their environment by discharging active oxygen species during phagocytosis. Perhaps nitric oxide might also play such a role.[14] It is unlikely that such a mechanism is operative in the case of viral infections such as hepatitis, but it may play a role in some infections.

Diabetes Mellitus-Induced Hemolysis

It has been suggested that episodes of diabetic acidosis may precipitate hemolytic episodes in persons with G6PD deficiency, but in one study no evidence was found that such an effect existed.[15] It has also been reported that hypoglycemia may precipitate hemolysis in G6PD deficiency.

Hereditary Non-SpherocyticHemolyticAnemia

It was in 1958, not long after G6PD deficiency was identified as the cause of primaquine sensitivity, that it was recognized that the enzyme deficiency could cause chronic hemolysis as well.[16] The syndrome of hereditary nonspherocytichemolyticanemia did not occur in persons who inherited the common, polymorphic variants of G6PD such as G6PD A- or G6PD Mediterranean, but rather in patients who had inherited rare mutations, designated class 1 because of their association with chronic hemolysis. The severity of hemolysis varies greatly. Although it is usually mild, the patient with G6PD Campina has transfusion-dependent hemolysis resembling thalassemia major. Presumably class 1 variants produce chronic hemolysis because the functional severity of the defect is so great that the erythrocyte cannot even withstand the normal stresses that it encounters in the circulation.[17] The functional severity in these patients is not usually reflected by the level of the enzyme as it is measured in the laboratory. The RBCs of patients with class 1 variants may have residual G6PD activity as high as 35% of normal when measured under standard conditions. The functional impairment that leads to the shortening of the RBC life span in these patients may

include such factors as susceptibility to inhibition by NADPH and in vivo lability.[18] Possibly the most consistent common feature of class l variants is the location of the mutation. In the great majority of cases, it is in the region of the putative NADP-binding or glucose-6-phosphate binding site of the molecule.

Neonatal Jaundice

Neonatal jaundice is one of the most life- and health threatening consequences of G6PD deficiency, and kemicterus may occur in these It is often erroneously assumed that the jaundice is the result of hemolysis.[19] However, this is apparently not usually the case. Anemia is not present in G6PD-deficient infants that develop neonatal icterus. Instead of the icterus being a manifestation of accelerated RBC destruction, it now seems likely that it is largely the result of the impairment of liver function, presumably because of a deficiency of the enzyme in the liver.[20] It is entirely possible that some shortening of RBC life span also plays a role. Neonatal jaundice has occurred primarily in Asian and Mediterranean infants. In one study, G6PD Aures has been associated particularly high incidence of jaundice. Early reports from the United States suggested that African-American infants did not have a significantly increased incidence of neonatal jaundice. However, anecdotal observations from the United States and surveys in Jamaica and in Africa all suggest that an increased incidence of neonatal icterus may occur also in infants with G6PD A-.[21]

Transfusion with G6PD-Deficient Blood

There is evidence that G6PD-deficient RBCs maintain viability less well than do normal cells even without being subjected to oxidative stress. However, the consequences of transfusing a single unit of G6PD-deficient RBCs into an adult are probably minor.[22] It has been pointed out that in the case of G6PD A-, the number of cells that would be destroyed if a hemolytic stress occurred would be no greater than the number of nonviable cells in a unit of blood nearing its expiration date. Transfusion of G6PD-deficient blood may be an issue of greater potential importance in parts of the world in which the incidence of the defect is very high and where more severely deficient class 2 variants such as G6PD Mediterranean are prevalent.[23] In such areas, it is possible for a patient to receive, by chance, several units of deficient blood. In one instance, it has been suggested that fatal hemolysis occurred in a young woman as a result of receiving G6PD-deficient blood, but the reports of such severe consequences are not themselves convincing of a cause-andeffect relationship. In a controlled study, only minor increases in bilirubin levels were found in individuals receiving a unit of

severely G6PD-deficient blood, but the changes might be greater if a hemolytic stress were present.[24] In general, it has not been the practice to screen blood bank blood for G6PD deficiency, even in areas in which the gene frequency is very high. However, caution is justified in the exchange transfusion of newborn infants. Here, in contrast to adults, the proportion of deficient cells could be very high, and the products of Hb catabolism disposed of inefficiently by the immature liver.[25]

Other Manifestations of G6PD Deficiency

It is reasonable to assume that a genetic trait that has reached such high frequencies in many populations that it is carried by some 200,000,000 persons would not have a readily apparent effect on fitness. For this reason, if no other, it has been generally assumed that those who carry polymorphic genes for G6PD deficiency would not suffer from any morbidity.[26] Nonetheless, a number of studies have suggested that G6PD-deficient individuals might, even in the absence of any stress, have some clinical abnormalities.

Tissue Distribution of The Deficiency

Early studies indicated that the deficiency of G6PD activity was limited to the RBCs; liver and leukocyte activity was reported to be normal, and it was even suggested that the defect might not be in the G6PD gene itself, but rather some other gene that influenced the stability of the enzyme in the erythrocyte.[27] Platelet activity was found to average about 40% of normal. These studies were probably performed on patients with G6PD A-, and subsequent investigations in patients with more severely deficient variants indicated that other tissues were indeed involved in G6PD deficiency.

Life Expectancy

Large-scale studies have assessed the effect of G6PD A- on the overall health of Afro-American veterans. In an investigation of 1,413 black males Petrakis et al found that the incidence of G6PD deficiency was 12.1% in the 5- to 20-year age group, 5.6% in the 21 to 49 year age group, and only 3.8% of those above the age of 49.[28] While acknowledging that there might be a number of explanations for this, they concluded that G6PD-deficient subjects had a reduced life span.[29] However, this seems unlikely in view of the fact that it would require a very high excess mortality rate among persons with G6PD deficiency. Indeed, a study of 65,154 black male patients admitted to US Veteran's Administration

hospitals showed no increased mortality among patients who were G6PD deficient and no significant difference in the mean ages of G6PD-deficient and nondeficient patients.[30]

Cancer

Epidemiologic studies suggested to some that the incidence of cancer may be lower in G6PD-deficient person. However, these investigations were generally based on screening methods that do not efficiently ascertain G6PD deficiency in heterozygotes, and even in hemizygotes who have a disorder that might decrease lU3C life span.[31] Indeed, in one study it was shown that the RBC G6PD activity of cancer patients is higher than that of controls. More recent studies tend not to show any differences between the incidence of cancer in G6PD-deficient and normal subjects.[32]

Diagnosis

Detection of G6PD deficiency

Before the underlying defect, G6PD deficiency, had been uncovered, two methods for detecting individuals sensitive to the hemolytic effect of primaquine had been developed, the Heinz body test and the GSH stability test.[33] Although still occasionally used, these surrogate tests are obsolete and no longer have a role in the diagnosis of G6PD deficiency.[34]Instead, quantitative assays or screening tests that detect severe deficiency should be used to diagnose the disorder.

Quantitation of G6PD Activity in Erythrocytes

The simplest type of quantitative assay measures the reduction of NADP to NADPH in the presence of glucose-6-P and hemolysate.[35] In reality, this type of assay measures both G6PD and 6-phosphogluconate dehydrogenase (6-PGD) activity.[36] In the reaction mixture, as in the cell, the immediate product of the G6PD reaction, 6-phosphogluconolactone is converted to 6-phosphogluconate which serves as substrate for the 6- PGD reaction. Thus, 2 moles of NADP are reduced for each mole of glucose-6-P consumed in the mixture.[37]Although methods that measure G6PD activity independently of 6- PGD deficiency have been available for many years, such methods have little additional utility in diagnosing the deficiency state, because 6-PGD does not usually limit the rate of the reaction, particularly in G6PD-deficient individuals.[38]

Screening for G6PD Deficiency

In hemizygous males who are not undergoing hemolysis, as will be found in population surveys, semi-quantitative or nonquantitative screening methods are entirely adequate.[39] Dye reduction tests, tirst introduced by Motulsky and Campbell-Kraut as the brilliant cresyl blue decolorization test, have been widely used.[40] Other receptors for the electrons from NADPH generated in the G6PD and 6-PGD reactions include methylene blue, MTT tetrazolium, and methemoglobin.[41] A test in which protection against denaturation of Hb under oxidative stress serves as an endpoint has also been developed.[42] Although all of these tests are still sometimes used, particularly in population surveys, they have largely been replaced by the fluorescent spot test, in which the generation of NADPH is detected directly visually under ultraviolet light.

Detection of G6PD Deficiency in Patients Undergoing Hemolysis.

While the diagnosis of deficient males ordinarily poses no special difficulties, the same cannot be written about the detection ofG6PD deficiency in patients with some of the milder G6PD-deficient variants (class 3) undergoing a hemolytic episode.[43] Because the older members of the RBC population are selectively removed in patients with variants such as G6PD A-, leaving the younger cells with nearnormal activity in the circulation, a screening test may give quite normal results, at least for a week or two after the hemolytic episode. The same problem in diagnosis does not exist in the case of severe (class 2) variants because in these variants, even the very young cells are severely enzyme deficient.[44]

Several different approaches may be used to diagnose patients who have just undergone hemolysis. The simplest is merely to wait for a week or two or to perform family studies. Alternatively, one may deplete the sample being studied of reticulocytes by centrifugation. The denser cells, although not truly old as has sometimes been believed, are depleted of very young RBCS.[45] Accordingly, it has been found that even during hemolysis, the dense fraction of cells is G6PD deficient. Another approach is to compare the activity of G6PD with that of another age-dependent RBC enzyme such as hexokinase or glutamic oxaloacetic transaminase. This approach has been used also to detect the G6PD A- genotype in patients with sickle cell disease, in which the mean RBC age is greatly decreased. The most powerful approach for establishing the diagnosis in the context of hemolysis is analysis of genomic

DNA obtained from circulating leukocytes . Neither the presence of young erythrocytes nor, for that matter, of transfused cells confounds the results obtained from such an analysis.[46]

Treatment

When hemolytic episodes occur in G6PD-deficient individuals, the inciting agent, drug or infection, should be removed whenever possible. However, in patients who have class 3 variants such as G6PD A-, it may be possible to continue essential drug therapy with careful monitoring of the blood count.[47] Blood transfusion is only occasionally required to support patients who have undergone severe hemolytic episodes, usually in patients with favism.

It has been suggested that attacks of favism may be ameliorated by the administration of desfemoxamine. In one study patients with favism who received a single 500-mg dose of desfemoxamine and packed RBC transfusions had a shorter duration of hemoglobinuria, greater rise in Hb level and more rapid drop in reticulocyte count than control patients who received packed cells alone.[48] However, it was not clear that both groups received the same volume of transfusion.

To permit NADPH to be produced by a different route, xylitol administration has also been proposed as a way to prevent or treat hemolysis of G6PD deficiency. Clinical studies in which two severely G6PD-deficient volunteers were pretreated with 10 g xylitol per day and then given primaquine and 20 g xylitol per day showed no protection against hemolysis.[49]

It has been suggested that vitamin E, by virtue of its antioxidant effect, might protect against chronic hemolysis in G6PD deficiency causing chronic hemolyticanemia. Some studies have shown a favorable response to this vitamin; others have not.

The most dangerous consequence of G6PD deficiency is neonatal icterus. Kernicterus has been documented repeatedly in populations in which class 2 variants are common and it has been pointed out this is an important preventable form of mental retardation. Phototherapy has been used to reduce bilirubin levels, and phenobarbital has been used prophylactically with some success.[50] Agar, given to reduce bilirubin reabsorption, was found to be ineffective. When the bilirubin level exceeds 20 mg/dL exchange of transfusion is required but G6PD-deficient blood should not be used for this purpose.

Abstract

Aim:
The aim of this research is to evaluate the general dental practitioners knowledge of dental radiography .

Objective:
Dental radiographs is one of the principal diagnostic methods used in dentistry.The safe and effective use of x-ray equipment is important to the protection of the patient and members of the dental team.

Materials and methods :
The data was collected from 50 general dental practitioners at self convenience using a structured questionnaire consisting of 9 item questionnaire.The sample was selected based on inclusion criteria and exclusion criteria.Inclusion criteria includes undergraduate,postgraduate and chennai dental practitioners. The exclusion criteria includes the students and dental radiograph assistants.
In the questionnaire, details were asked about the age of the intraoral radiographic unit, kVp and mA of the equipment, the type of timer on the machine and about the geometry of the machine and the geometric technique used for intraoral radiography.Furthermore, the questionnaire contained questions about the type of intraoral detectors that were used and whether the dentists were also using panoramic machines and, if so, which type of detector they had. Among the possible answers, one option was ‘‘no idea’’.The data thus obtained was subjected to statistical evaluation.

Conclusion:
The results of this study showed that the knowledge of dentist in South Chennai regarding dentomaxillofacial radiology is excellent.The level of awareness of practitioners regarding radiation hazards and safety was found to be acceptable.

Keywords:*general practitioners,knowledge, radiology, radiation protection,exposure.*

Introduction

As a dental professional, the utilization of radiograph for finding and further treatment is significantly more regular than different fields of medicine.It is accounted for that around

45% of dental patients require radiographs for determination. [1]Dental radiographs is one of the essential demonstrative techniques utilized as a part of dentistry.Intra oral and extra oral radiographs are two sorts of radiographs available.The sheltered and powerful utilization of x-beam hardware is imperative to the assurance of the patient and individuals from the dental team.Its assumes a critical part in the identification of oral disease.[2]Exposure to such radiation is related with an expanded hazard in the long haul of threatening sickness in those persons.Furthermore, it is accepted that the likelihood of event of these antagonistic impacts is straightforwardly corresponding to the level of presentation, with no measurements threshold.The dangers related with the vital introduction to ionizing radiation might be generous, and must be limited through careful adherence to great practice.[3]

Specialized advances in radiological equipment significantly affect lessening of radiation dosages to patients during intra oral and extra oral radiographs. During extra oral radiography, the utilization of uncommon earth escalating screens has diminished the radiation presentation significantly.[1,4,5]Although the quantity of radiographs taken every day in essential dental care is over the top, the most serious hazard emerges when there is proof of poor picture quality or non-diagnostic images inferable from poor specialized information and the insufficient handling of films [6-10]. It has been evaluated that the disposal of non-beneficial examinations could prompt a 30% lessening in the aggregate populace measurements, got from medical radiology.[11] Dental hygienists assume an imperative part in handling and they should accept the accountability for poor preparing rehearses, the majority of which concern not supplanting preparing arrangements as oftentimes as required, overdeveloping and overfixing. Accordingly, numerous dental practitioners tend to build the presentation time to make up for the disgraceful preparing, therefore expanding the radiation measurements to patients. [12]

For dispensing with unnecessary X-beam examinations, each expert who works X-beams ought to be appropriately prepared as per the Ionizing Radiation Medical Exposure Regulations 2000.[13] We live in an ocean of radiations. We are constantly exposed to naturally occurring ionizing radiation i.e.,background radiation and furthermore presented to ionizing radiation from manmade sources, for the most part through medical procedures.On an average, doses from a diagnostic X-ray are much lesser, in dose effective terms, than the natural background radiation.Radiation has turned into a part of present day living, achieving each section of our general public. The essential hazard from dental radiography is radiation actuated malignancy. The writing on conceivable destructive impacts of expert analytic presentation for dental specialists isn't steady. The hazard required with dental radiography is surely little in correlation with numerous different dangers that are a typical piece of regular daily existence. In any case, no premise exists to accept that it is zero. Likewise, the biologic impacts of ionizing radiation ingested during dental radiography are questionable. The radiographic examination utilized as a part of all fields of medicinal administrations and adds to the advancement of the well being, both separately and broadly. Radiographic examination has a basic impact of dental practice. Certain measure of radiation is unavoidably conveyed to patients, it ought to be as low as reasonably achievable [ALARA]. International Commission for Radiation Protection [ICRP] is the administrative body which sets down

standards for radiation security at the universal level. In India, it is the Atomic Energy Regulatory Board [AERB] which gives the standards to radiation assurance.

AERB prescribes standards for reasonable dosages of radiation from X-beam tubes, the protecting required for the dividers of a X-beam tube room, the lead equal protecting attire to be worn by radiation specialists and sets down safe measurements limits for radiation laborers and for the overall population.Before undertaking any radiological examination, it is important that the provider comprehends the potential dangers and the advantages of radiation. The dangers can be stochastic [of which likelihood increments with dosage] and deterministic [of which severe increments with measurement].Cancer induction and hereditary effects are stochastic impacts and blood dyscrasias,cataracts and imparired fertility are cases of deterministic effects.Biological effects of ionizing radiation are gathered into stochastic and deterministic effects. Over a specific decided dosage of radiation organic harm starts to show up, this is called as deterministic impact. Stochastic impact is that in which there is no specific dosage level above which natural change happens in the body.

Ionizing radiation causes both the impacts relying upon radiation doses and body's reaction to these radiations. Dental practitioners and in addition patients are more inclined to the danger of stochastic effects because of its lack of a dose threshold limit. The positive parts of diagnosis of disease and detection of disease should be considered while assessing the risk of impacts of radiation. It is essential for dental practitioner to refresh their insight about new patterns in analytic strategies, protective measures, etc.This can be accomplished by methods for proceeding with training, continuing education, journals,workshops, and other media.In India, diagnostic radiation facilities are administered by Atomic Energy Regulatory Board [AERB].The role of the AERB is to guarantee that utilization of ionizing radiation and atomic vitality in India does not make undue hazard the well being of individuals and the environment.It is required to enlist all diagnostic radiation facilities in e-Licensing of Radiation Application [eLORA] system of AERB. From December first, 2013, it is mandatory for dental specialists and dental institutions to enroll in eLORA and get a license to operate dental X-ray units, panaromic machines, and cone bean computed tomography. It is additionally essential for manufacturers of X-ray machines to get a license available to be purchased in India by AERB.

The current radiation protection standards are based on 3 principles : Justification of a practice, optimization and dose limitation.In spite of the fact that the radiation dosage levels in dental practice are generally low, one ought to think about the combined impact of repeated exposures. There ought to be a making progress toward radiation assurance measures in the private dental offices.[14]There is an association between knowledge and the use of low-dose techniques and attitudes towards risks.[15]A dental professional should always be prepared to improve his or her knowledge through continuous education, it is a well-known fact that this is more likely to occur if the continued education is mandatory for all dental professionals, for whatever local or federal reasons.[16]

The reason for performing this study was to alert the dental professional societies that more attention should be paid to radiation protection in dentistry in our country. The aim of this research is to evaluate the general dental practitioners knowledge of dental radiography .

Materials and method

Data was collected from 50 general dental practitioners using a structured questionnaire consisting of 9 item questionnaire.The sample was selected based on certain inclusion and exclusion criteria.

Inclusion criteria :

1. Undergraduate
2. Postgraduate
3. Chennai dental practitioners

Exclusion criteria:

1.Students

2.Dental radiograph assistants

In the questionnaire, details were asked about the age of the intraoral radiographic unit, kVp and mAofthe equipment, the type of timer on the machine and, about the geometry of the machine and the geometric technique used for intraoral radiography.Furthermore, the questionnaire contained questions about the type of intraoral detectors that were used and whether the dentists were also using panoramic machines and, if so, which type of detector they had. Among the possible answers, one option was ‘‘no idea’’.The data thus obtained was subjected to statistical evaluation.

Result

Table-1 responses from the study subjects to the questionnaire in percentage[%]

Intra - Oral Radiographic Machine	Condition	Percentage
Practice dates from	After 2000	100%
Works at (Kv)	70Kv	20%
Works at (Kv)	60Kv to 70Kv	80%
Works at (mA)	4 or 8mA	92%
Works at (mA)	No Idea	8%
Timer	Digital Timer	100%
Shape	Long Cone	6%
Shape	Short Cone	94%
Rectangular Collimator	Yes	20%
Rectangular Collimator	No	80%
Parallel Technique	Yes	18%
Parallel Technique	No	82%
Works with	Digital Censor - CCD	24%
Works with	Digital Censor - PSPP	76%
Panaromic Machine Disposal	No	10%
Panaromic Machine Disposal	Yes - Analogue Film	80%
Panaromic Machine Disposal	Yes - CCD Technology	10%

Discussion

As mentioned above the data was collected from 50 general dental practitioners using a structured questionnaire consisting of 9 item questionnaire.The sample was selected based on certain inclusion criteria and exclusion criteria.Inclusion criteria which includes the Chennai dental practitioners,undergraduates,postgraduates and Exclusion criteria includes Students,dental radiograph assistants.Regarding the age of the intraoral radiographic equipment used by the questioned population of chennai dentists, it was found that almost 100%[50 dentist] were using radiographic machines for intraoral radiography equipment that was after 2000.

As the answers about the tube voltage of the intraoral equipment was mild difference the answers were condensed into two groups. Therefore, tube voltage ranging from 60 to 70 kV was considered as one category. 80%[40 dentist]of the equipment used in South chennai dentist was reported to operate between 60 and 70 kVp. ,whereas 20%[10 dentist] claimed to be working at a tube voltage of 50 kVp.

The majority of the South Chennai dentists were using 4 or 8mA[easy to change] equipment for intraoral radiographs ; 8%[4 dentist] claimed they not knew what they were working .

100% [50 dentist]claimed to be working with a digital exposure timer, whereas none said they were still working with a manual [clock-like] exposure timer.

It was found that 94% [47 dentist]said that they were working with a short cone geometry, whereas 6% [3 dentist]claimed to be working with a long cone geometry.

20% [10 dentist]said they were using a rectangular collimator.80%[40 dentist] responded that they were using circular collimatior.

18%[9 dentist]claimed to be working with the parallel technique, whereas 82%[41dentist] said they were working with the bisecting angle technique.

76%[38 dentist]of the dentists in South Chennai were still using PSPP sensor films for intraoral radiography. 24%[12 dentist] had digitized to intraoral sensors as charge coupled device [CCD].

About 10% [5 dentist]of the dentists has no intention idea what sensor they using.10%[5 dentist] of South Chennai dentist don't not posses a dental Panaromic machine. Others 80% use analogue films and 10% [5 dentist]use CCD technology.

A dental professional should know his or her equipment and it is expected to know the main guidelines on radiation protection.The overall conclusion of this study,is that a great deal of work done to ameliorate the quality of radiographs and the knowledge and attitude of general dental practitioners regarding dentomaxillofacial radiology.[2] This is a task for dentomaxillofacial radiology specialists, who will have to concentrate in the first place on undergraduate teaching and then on postgraduate teaching. The latter is not less important than the first as the working dentist population needs to change their attitude regarding radiation protection and dentomaxillofacial radiology general knowledge. [3]This has also been stressed in other surveys. From the results ,it is evident that continued education in dentomaxillofacial radiology is essential, especially when considering a change from analogue to digital radiology.[4]That 92%[46 dentist]of the dentists in the present survey claimed to be working with a short cone radiographic machine is probably biased by the fact that they are not aware of the difference between a short cone and a short spacer cone, which

is also called a beam indicating device or position indicating device.[17]It can be assumed that dentists owning a machine with a short spacer cone, because the manufacturer positioned the focus near the rear end of the machine, gave the wrong answer. Therefore this result should be interpreted with care. The opposite for long cone could also be the case, of course.
[18]The results are, therefore , excellent.This could mean, for instance,increased in the number of hours of under and /or postgraduate education. If this can be decided by the local authorities and enforced at university level, it had a chance of succeeding. However, at present, every university has its own curriculum.And as known from other studies, it is not always easy to change curricula and convince faculty staff colleagues of this issue.[19]
Regarding the knowledge of Chennai's general dental practitioners, there are various reasons for the results of this questionnaire being excellent . Perhaps the quality and quantity of the undergraduate education is good.However, it is the personal impression that, for many years, dentomaxillofacial radiology has been taught at every university in the country by medical radiologists or general dentists with specific dentomaxillofacial radiology training.The major problem with the undergraduate education is the number of hours that should be dedicated to dental radiology.The age of the dentists was not assessed and also the university where they had studied. Age was not considered an important question in this study, as the age of a dentist does not always reflect that person's knowledge of dental radiology.Furthermore, it is known that not every young dentist starts with new equipment and, vice versa, that not every "older" dentist is working with old equipment. Therefore, the age of the intraoral radiographic equipment was considered more important and more relevant as a question.[20]The level of knowledge and the attitude of dentists regarding radiation safety will have a direct impact on patient exposure to radiation [Shahab et al. 2012]. Many studies have been done to determine the knowledge and attitude of dentists regarding radiation safety.
Shahab et al reported a study pertaining to radiation safety to assess the knowledge of dentists with regard to basic information in relation to radiation protection and methods of reducing the radiation dose to the patient. The majority of dentists did not employ appropriate procedures to decrease exposure to unwanted radiation.[21]
Mutyabule and Whaites conducted a study to assess radiation protection measures in dental practices in Uganda. It was found that operators lacked sufficient knowledge regarding radiation safety protection measures.[22]
Apsassessed dentists' knowledge regarding radiation safety. The dentists were asked about various methods of dose reduction to the patients. The results of the study highlighted the need to increase knowledge of dental practitioners regarding radiation safety and methods of dose reduction.[23]
Lee and Ludlow assessed the attitude of dentists regarding radiation safety. The dentists were asked about primary knowledge of radiation safety and the method of reducing the dose to the patient such as speed of the film, collimation of the X-ray tube and the regular use of shielding. Results of the study confirmed that there is a demand to reinforce the dentist's working knowledge about the issue of radiation safety.
Math et al assessed the understanding of dentists regarding radiation safety standards with regards to the X-ray machine, collimation of the tube, regular use of a film holder, shielding

and the position of the operator during radiation exposure. The result of this study also highlights the need to increase the practitioner's awareness and attitude regarding radiation hazard and use of appropriate methods to reduce the radiation dose.[24]

Jacobs et alconducted a study regarding the perceptions of the dentists of radiation protection. The results of this study concluded that there was a need to apply strict guidelines toward radiation safety.[25]

Majority of the practitioners still followed the position and distance rule, few were found to be using lead barriers while mere used lead aprons and some using a combination of various safety techniques. Distance in radiation protection refers to distance from the source and the individual. As the distance increases, radiation exposure reduces. Moreover, shieldingincludes both protective barriers such as lead shield and personnel protective measures such as lead apron. Ninety-eight percent reduction in scattered radiation and attenuate dose to 0.04 µR can be achieved using lead aprons.Patient should wear thyroid collar during radiation exposure as it reduces attenuation of scattered radiation to 92%[46 dentist].Proper shielding from radiation and by increasing the distance from source protect radiographer as well as patient for unnecessary exposure to radiation. According to position distance rule, radiographer position should be at least 6 feet from the source at an angle of 90 to 135° to the central ray of X-ray beam.

Conclusion

The results of this study showed that the knowledge of dentist in South Chennai regarding dentomaxillofacial radiology is excellent.This emphasizes that there is better under and postgraduate education in dentomaxillofacial radiology in Chennai. The present report is therefore an important statement for the dental professional society.The level of awareness of practitioners regarding radiation hazards and safety was found to be acceptable. However, implementation of their knowledge with respect to patient and personnel safety was found wanting. Insisting that they follow the protocols and take necessary safety measures by means of continuing medical education programs, pamphlets, articles, and workshops is strongly recommended.From the time of its discovery, X-rays have played a vital role in the field of medical and dental science. Ranging from diagnostic to therapeutic applications, the use of X-rays is manifold. Probably, the most widespread application is in the field of dentistry from the simple diagnosis of incipient caries, multiple fractures to aiding in more complex procedures such as precision implant planning. The modalities at the disposal of dentists range from intraoral radiography to cone beam computed tomography. During the course of their training, all health-care personnel are trained regarding radiation hazards and requisite safety measures. However, the sincerity with which the matter is considered needs to be assessed from time to time. In the present study, we attempt to evaluate the awarenessand validate the knowledge of radiograpy among general dental practitioners in Chennai, India.Protection of one's self and patient from all kinds of health hazards is the hallmark of concerned doctors. The AERB recommendations should reach out through the dentists'

platform [e.g., IDA] to the dental practitioner. Better “safe than sorry” remains no more a virtue but a fundamental necessity.

Abstract

To review the use of genetic biology in age determination.Chronological age fails to provide an accurate indicator of the ageing process. Biological age estimates the functional status of an individual in reference to his or her chronological peers on the basis of how well he or she functions in comparison with others of the same chronological age. This concept leads to the notion that biological age can be calculated for any given age group, thus being applicable to unselected pedigree members from the general population.The development of a biological age estimate using a combination of reliable quantitative biomarkers will also provide an instrument for assessing the effectiveness of any experimental manipulation or intervention in human aging. The search for genes which contribute to aging will benefit from the development of such a measure of biological aging of an organism as a whole.

Key Words:*Genetic biology, Ageing, Biomarkers, Skeletal age, Biological age.*

Introduction

Biological (synonymous with "functional" and "physiological") age has been proposed as an elective phenotype of intrigue. Since tissues age at various rates and in light of the fact that sicknesses change massively among people, people turn out to be progressively unique in relation to each other with age[1]. Ordered age neglects to give a precise pointer of the maturing procedure. Organic age gauges the utilitarian status of a person in reference to his or her sequential companions based on how well he or she works in correlation with others of the same ordered age. This idea prompts the thought that organic age can be computed for any given age gathering, accordingly being pertinent to unselected family individuals from the overall public. Diverse individual rates of the maturing procedure prompt contrasts amongst ordered and natural age, in this way singular estimations of organic age can shift broadly at any given sequential age, and at last are relied upon to relate to the bury singular varieties in life span and timing and additionally extent of spin-offs of the maturing process[2].

It has been suggested that natural age may fill in as a marker of a person's general wellbeing status, staying sound life expectancy, and dynamic future. Organic age may help in distinguishing people in danger for age-related disarranges, filling in as a measure of relative wellness, and foreseeing handicap in later life and mortality free of ordered age Other attributes, for example, slightness and allostatic stack, have been proposed as elements to consider while surveying heterogeneity of wellbeing status in elderly people, however these builds are not appropriate for an investigation of moderately aged people.

Individuals who work inadequately are believed to be "naturally more established" than their sequential companions; on the other hand, individuals who work well may be regarded "organically more youthful." The idea of organic age might be best spoken to by the development of a file got from a few organic parameters of a life form (supposed biomarkers of maturing), which are firmly identified with the support of life and associated to some degree with ordered age[3]. Investigation and approval of biomarkers remains a need in gerontology. Since tissues and organs age at various rates, there is a need to get biomarkers from numerous frameworks and to join them in the most proficient approach to reflect general maturing of a living being.

The majority of the proposed strategies for organic age assurance utilize far reaching multifactorial estimating frameworks or batteries of tests, incorporating an expansive number of biochemical, physical, mental, and utilitarian parameters that change with age[4]. The more far reaching the decision and evaluation of parameters of dysregulation in all the critical administrative frameworks, the better the capacity of their mix to foresee results. Some physiological frameworks might be more significant than others to the rate of maturing then again, some biomarkers can reflect dysregulation of numerous frameworks. The look for worldwide and framework particular markers will proceed until there is a superior comprehension of the connection between the imperative real frameworks.

The most clear biomarkers incorporate silver hair, presbyopia, and skin inelasticity. An expanded survey and dialog of biomarkers and their connection with age and prescient capacity of wellbeing results was given by Anstey and associates 10 years ago[5]. Most as of late, new biomarkers of maturing and new batteries of tests have been proposed, incorporating changes in telomere length, cross-connecting of collagen, glycosylated hemoglobin, beat wave speed, hearing misfortune, number of solid teeth and additionally sarcopenia. Seeman and partners additionally propose the utilization of fiery markers, coagulating variables, and safe capacity tests as biomarkers[6].

Numerous mainstream biomarkers decay generally directly with age with a slant of <1% per annum. Albeit certain biomarkers may veer off from linearity in a few bits of the age dispersion, a straight relationship is typically proposed for most biomarkers as a best fit. Psychosocial factors demonstrate minimal relationship with age, though measures of respiratory capacity demonstrate the most grounded affiliations. By and large, educational biomarkers should: a) foresee, superior to anything sequential age, decreases in one or a few organ frameworks as well as the probability of a malady occasion; b) be exceptionally connected with age-related loss of capacity, as opposed to just being associated with ordered age or survival; and c) be insignificantly obtrusive and promptly noticeable, dependably estimated, ideally on a quantitative scale[7].

We understand that the biomarkers by and large chose at introduce are simply previews of vital administrative frameworks; there is no data on framework elements if each biomarker is estimated just once. Despite the fact that the predominance of longitudinal over cross-sectional information is entrenched, its leeway in investigations of maturing might be

especially huge in light of the fact that longitudinal examinations allow the immediate examination of individual change and recognizable proof of elements related with that change[8]. A direct association with age that is expected for most biomarkers as a best fit may not generally be right because of deviation from linearity in a few bits of the age dispersion. An extra constraint of a cross-sectional estimation of natural age is an inability to represent bury singular contrasts in factors that are not identified with maturing. Each biomarker's change comprises of both honest to goodness maturing contrasts amongst people and contrasts not identified with maturing. A critical case of this is found in an investigation by Nakamura and partners, which demonstrated that hereditary variables may impact biomarkers at one time point as well as their rates of progress with time (age). There is an undeniable need to comprehend the status of the biomarker factors at various time focuses, and in addition to survey singular rates of natural age changes[9].

Choice of Biomarkers- Statistical Modelling

A fruitful future area of investigation in gerontology should focus on incorporating genetic profiles (variations in gene sequence and expression) along with other biomarkers of aging into prediction of health outcomes. Comprehensive studies, combining molecular genetic approaches with genetic epidemiology, gene expression profiling, proteomics, and functional genomic technology, will greatly accelerate the pace of discovery of genetic causes of aging. From a medical point of view, the endpoints of anti-aging therapy are clear: extending a healthy life span and maintaining and improving individual well-being, both physical and psychological, with the ultimate aim of exploring new ways of halting or delaying the onslaught of functional decline in elderly persons. Genotype information can be particularly useful in case–control studies ultimately, results of these studies will lead to developing novel intervention strategies, such as personalised geriatric medicine seeking to slow aging. It should become possible to assess a genetic risk profile for individuals that will enable them to rationally alter their lifestyle. Continuous efforts should be made to develop batteries of candidate genes and biomarkers of aging. As pointed out by Le Bourg: “Aging can be delayed if the right tool is discovered”.

The essential factors that have been utilized as an intermediary for maturing related attributes incorporate life span, absence of utilitarian decay, "successfull ageing," dynamic future (the

term of survival without disability), and wellbeing anticipation (survival with no one of a predefined set of disease, for example, cardiovascular infection, cancer, fracture, or dementia). In spite of the fact that there seem, by all accounts, to be built up methods to decide maturing related attributes, our comprehension of important hazard factor(s) for these results is still exceptionally simple. A basic situation is to utilize individual natural markers and covariates as indicator factors with one of the results as the ward variable[10]. In any case, the assessment of individual biomarkers (e.g., SBP, lipid measures, or hand hold) as essential indicators has been embroiled as a less proficient approach when contrasted with the utilization of rundown files. One of the key highlights of maturing considers has been the endeavor to choose an arrangement of factors that catches the "aggregate natural weight," which can be communicated as an element of watched singular hazard factors (biomarkers). In this way, Seeman and associates proposed a solitary rundown score (allostatic stack) as a measure of aggregate natural weight autonomous of result measures[6]. Further, Karlamangla and associates got a weighted synopsis score of hazard factors in view of standard connection investigation (hence characterizing allostatic stack restrictive on result measures)[11].

The kinds of strategies used to characterize composite factors incorporate those in view of basic midpoints or wholes of individual biomarkers, accepted examination, factor (central parts) investigation, and different straight relapse procedures. The propriety of these strategies relies upon the objectives of the investigation and the sort of information being examined. Reasonable lucidity and the basic rationale of picking these or different methodologies are key for the exactness of the examination.

One generally utilized strategy for natural age estimation is a different relapse of numerous biomarkers with age as the reliant variable. There are three normally utilized determination methods: forward choice, in reverse disposal, and stepwise relapse. Regardless of whether one uses forward determination, in reverse end, or stepwise relapse, these procedures are not guided by any substantive hypothesis—i.e., they utilize measurable calculations with little respect for the examination questions and additionally targets; and they don't really create the best model or an ideal choice of the subset of biomarkers. A typical issue with these strategies emerges when there are excess predictors[12]. Since in complex living beings, hypothetically, forms are for the most part related, changes in a single organ framework may influence numerous others. Notwithstanding, there are redundancies in compensatory frameworks in complex creatures that save work. There is accordingly a need to adjust the

want to incorporate however many qualities as could be allowed with the need to limit the quantity of attributes in the model.

Factor investigation has been proposed as a method for choosing factors instead of varieties of biomarkers of maturing. Primary part investigation is helpful to develop a straight blend among exceptionally perplexing, corresponded (colinear) biomarkers, and along these lines lessen the quantity of factors catching the maturing rate. The strategy gives rules to decide the quantity of parts to hold and the factor scores to characterize outline factors (primary components)[13]. In fact, a key part can be characterized as a direct mix of ideally weighted watched factors. When all is said in done, the bigger the span of the factor stacking for a variable, the more essential the variable is in translating that factor.

The capacity of both relapse conditions and factor answers for sum up crosswise over examinations isn't high. In any case, the two strategies are important as an estimation of an unpredictable system of natural maturing, and may distinguish various biomarkers that have reliably contributed a noteworthy piece of organic age changeability in numerous studies[11,12,13] A contrasting option to relapse incorporates the recursive parceling to recognize nonlinear examples of relationship among biomarkers. Development of weighting frameworks in light of accepted connection examinations has likewise been proposed, which shapes a straight blend of the factors from each set (called a sanctioned variable), with the end goal that the connection between the two standard factors is expanded. Karlamangla and associates utilized this way to deal with enable unequal weight to mirror a more practical situation in which the distinctive segments of the joined score contribute differentially to outcomes[11].

There is by all accounts a developing agreement with respect to the procedure for assessing organic age. Indeed, late examinations (counting our own) have acknowledged the accompanying factual definition: Biological age can be computed as a leftover between real age and anticipated age (from a measurably demonstrated blend of numerous biomarkers).

Biomarkers and Biological Age

There has been a hidden desire that a measure, for example, natural age ought to have the capacity to anticipate demise and incapacity freely of sequential age. Endeavors to assess the

prescient capacity of death by batteries of biomarkers started numerous years back. For instance, Uttley and Crawford built up a battery of biomarkers from pneumonic capacity (constrained expiratory volume), neuromotor execution, pulse, blood science, quality/adaptability, and anthropometric factors in their Mennonite tests. Organic age demonstrated along these lines did not definitively anticipate death[14]; be that as it may, a few individual biomarkers were related with higher relative hazard for mortality. Thus, Brant and partners found that circulatory strain, heart analysis, constrained expiratory volume, and visual sharpness were related with mortality in the Baltimore Longitudinal Study of Aging[15].

A contention could likewise be made that significant biomarkers ought not be required to anticipate mortality. Actually, the capacity of natural maturing records to foresee life traverse is a flawed rule beforehand used to approve these markers. There are numerous hazard factors that anticipate future in moderately aged individuals, yet are not firmly identified with a basic procedure of maturing, frequently in light of the fact that they are surrogates of weakness practices or particular infection chance. More critical is the capacity of a portion of the biomarkers and organic age measures to have the capacity to separate between antagonistic maturing related occasions, for example, stability, organization, or penchant to fall. An outline record of a few biomarkers ("allostatic stack") has been shown to be a noteworthy indicator of real wellbeing results, to be specific, mortality and decreases in psychological and physical working, both over a 2.5-year and 7.5-year development. Quite, none of the individual biomarkers, segments of this list, had solid prescient capacity for the above results, recommending that the outline list for sure measures a property past minor brokenness in one organ system[16].

Common and New Biomarkers

SBP, hold quality, constrained expiratory volume, cholesterol and glucose blood levels, and psychological and additionally neuropsychological information are the most regularly utilized biomarkers in investigations of natural age. SBP has been one of the beforehand examined biomarkers for a few reasons. There are changes in vascular solidness with maturing that influence SBP; these progressions might be because of the lessening in versatile consistence of maturing vascular tissues. In a longitudinal investigation of Japanese men, SBP essentially expanded over a 7-year interim ($r = 0.58$), and in a few cross-sectional examinations, SBP

likewise has been shown to connect well with age in both genders (r = 0.45 in guys and 0.50 in females)[17]. Heartbeat weight, a distinction amongst systolic and diastolic circulatory strain, logically increments with age because of dynamic hardening of corridors, and consequently may likewise fill in as a biomarker of blood vessel maturing.

Sarcopenia is showed as muscle quality and bulk diminish with age, basically because of the adjustments in muscle morphology. This for the most part is because of diminished extent and cross sectional territory of sort II filaments, in any case, single fiber investigation recommends that the contractile proteins may turn out to be less powerful with age. Hand grasp quality is known to be related with solid working in other muscle gatherings and with exercises of day by day living. In a few cross-sectional investigations, grasp quality corresponded with age (r = 0.61 in the two guys and females). Hand grasp quality predicts cause-particular and aggregate mortality and inability. Symptomatic hand osteoarthritis additionally has been appeared to be conversely connected with hold strength[19].

The histological changes in lung parenchyma, a decline in ventilatory muscle quality, and an expansion in lung consistence with maturing add to bring down crucial limit and expiratory stream rates in elderly people. Constrained expiratory volume in 1 second (FEV1) and constrained imperative limit (FVC) are the best measures of aspiratory work. Both essentially diminished with age (r = −0.60 to −0.75 in cross-sectional and −0.48 to −0.60 in longitudinal examination, for FVC and FEV1, respectively)[18,19].

Cross-sectional and longitudinal changes in cholesterol levels with maturing have been accounted for in both genders. Eminently, serum cholesterol levels expanded by 18% more than 15 years in ladies and by just 6% in men. LDL cholesterol levels likewise increment with age in most human populaces, and relate to higher cardiovascular pathology and mortality. HDL cholesterol levels have been appeared to be significantly higher in the posterity of Ashkenazi centenarians than in controls, proposing that HDL might be engaged with remarkable life span. A few examinations have discovered a diminished grouping of aggregate cholesterol in an elderly populace, maybe clarified by their deficient nourishment or lower physical movement. Age subordinate decrease of aggregate cholesterol levels has been recommended to be a marker of poor health[15,16,17,18].

Hindered glucose resilience and non-insulin-subordinate diabetes turn out to be dynamically more typical with propelling age, because of diminished hepatic affectability to insulin or insufficient emission of insulin. Coming about hoisted glucose focuses (hyperglycemia), specifically, potentiate damage to mitochondrial DNA. Blood glucose levels have been appeared to relate with age in Japanese men ($r = 0.17$ in cross-sectional and $r = 0.13$ in longitudinal examination).

Decrease in cerebral blood stream, white issue injuries, and a critical decrease in the quantities of mind cells add to intellectual decrease in elderly people. With expanding age, there is an expanded hazard for memory hindrance and additionally signs of age-related decrease of other psychological capacities in generally typical more seasoned grown-ups. Along these lines, in the Framingham Study, the most established members had the least execution levels estimated by a neuropsychological test battery (be that as it may, they likewise have had the least years of formal instruction). When all is said in done, the mean execution of less instructed elderly people was fundamentally poorer than that of their better taught peers[20].

Skeletal Biomarkers

The process of bone involution seems to be a general phenomenon and a normal manifestation of tissue atrophy with age. After the skeleton has reached maturity, bone remodelling is responsible for the complete replacement of old bone tissue with new tissue. With advanced age, the placement and quality of new bone are altered[21]. This alteration is caused by the change in areas of remodelling due to disease, by variations in muscle strength, and by trauma. Also, at different phases of life during which there are various kinds of work and leisure activity, bone activity may be altered. The amount of bone reformed and replaced during the remodelling cycle progressively decreases with advanced age due to decreased proliferative capacity of osteoblasts as well as to cumulative damage of uncorrected molecular errors. The longer an individual lives, the more remodelling cycles he or she undergoes, and the more such errors accumulate[22]. Finally, the contribution of catabolic illness, such as surgery, injury, palsy, and immobilisation, may contribute to rapid bone degeneration. The net result of the age-related bone changes in older persons is chronic degenerative disease, which is characterized by the loss of bone mass and bone strength, development of fragility, and the alteration of bone morphology. These processes involve

both cortical and trabecular bone compartments, juxtaarticular regions, and bones of axial and appendicular skeleton, and are common in humans of different ethnic groups, both modern and prehistoric.

There is a strong correlation of age-related skeletal features with the state of many vital functions ,age-related conditions of different bodily systems, and ultimately survival rates. For example, lower bone mineral density and higher osteoarthritis are associated with a higher risk of mortality independent of age and comorbidities. In particular, low bone ultrasound indices have been associated with a higher risk of all-cause and cancer mortality.

Adaptive mechanisms, which compensate for skeleton's deficient remodelling, are also evident in degenerative bone disease. Thus, endosteal expansion causes subperiosteal outgrowth; excessive bone resorption (such as that occurring when the skeleton is unloaded) brings about heterotopic calcification in neighbouring soft tissues[24]. Similarly, new bone formation is demonstrated by endochondral ossification of enthesis fibrocartilage and development of osteophytes. Longitudinal studies have shown that incident bone degenerative traits never regress. These features of the skeleton make it an attractive organ system for assessing biological age. Bone changes are relatively stable, unlike most non-skeletal biomarkers that may vary seasonally or diurnally or may be dependent on external conditions.

Age-related bone and joint changes manifest as visible and measurable traits, which has facilitated paleoanthropological and forensic applications of skeletal ageing methods and has ultimately paved the way for the development and usage of a radiographic (osteographic) scoring system as an integrative measure of adult bone ageing[25].

Conclusion

Human aging is a complex and irreversible process that is genetically determined and influenced by the environment. The study of aging genetics in humans is an enormous challenge. The complexity of the aging phenotype and the challenges inherent in the study of human aging oblige researchers to resort to models and extrapolations. Because different individual rates of the aging process lead to differences between chronological and biological age, the deviation between the actual age and age predicted using validated measurements may be one approach to estimating the biological age of an individual. An interdisciplinary

approach is needed to further develop reliable methods of biological age evaluation and to validate this phenotype as a predictor of important health outcomes of aging. The development of a biological age estimate using a combination of reliable quantitative biomarkers will also provide an instrument for assessing the effectiveness of any experimental manipulation or intervention in human aging. The search for genes which contribute to aging will benefit from the development of such a measure of biological aging of an organism as a whole. Empirically, not all valid biomarkers proposed in one study may be replicated in other samples, due to missing measurement or differences in technique. Until a consensus on a minimal set of biomarkers is achieved, it would be premature to recommend the use of biological age for changes in policy such as life insurance, elderly driving, and retirement benefits. Differences between ethnic and geographical groups, both in terms of their biological age (at a given age) and its rate of change, as well as genetic effects of aging-related genes in different races, are almost totally unexplored. Similarly, the extent to which biological age interacts with sex is not clearly established.

Green Tea in Oral Health

S.Thaminee[1],Nithya Jaganathan[2],Ashok V[3],
Graduate Student[1],Professor[2], Department of Oral Pathology, Reader[3], Department of Prosthodontics[3],
Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstract

Green tea is biologically important in oral protection.It is an antioxidant, antimutagen, antimicrobial, anticollagnese contains fluoride that prevents the dental carries. It is one of the most consumed beverages, which also provides a very good health. Green tea induces the biological activity due to the presence of Polyphenols namely catclines. Cateclines are considered to be the most predominant among polyphenols egigallo catechin 3 gallatecatechinswhich are proved to be helpful in the treatment of chronic diseases. It protects against bacterial induced dental carries.

Key Words: *Polyphenol, Anti Oxidant, Anti Viral, Dental Carries, Bleeding Gums, Oral Cancer, Periodontal Pathogens*

Introduction

Green tea is important source of polyphenol antioxidants.Green tea protects against bacteria that inducing dental caries. Generally, green tea defends healthy cells from malignant transformation and locally has the ability to induce apoptosis in oral cancer cells (10). There is a need for more clinical and biological studies to support guidelines for green tea intake as part of prevention and treatment of specific oral pathology(1). The effect has been attributed to the poly phenol content which is known to induce apoptosis of tumor cells and has little or nil effect in normal cells (9).Green tea is particularly rich in health-promoting flavonoids (which account for 30% of the dry weight of a leaf), including catechins and their derivatives. The most abundant catechin in green tea is epigallocatechin-3-gallate, which is thought to play a pivotal role in the green tea's anticancer and antioxidant effects. Catechins should be considered right alongside of the better-known antioxidants like vitamins E and C as potent free radical scavengers and health-supportive for this reason. It has been suggested that green tea also promotes periodontal health by reducing inflammation, preventing bone resorption and limiting the growth of certain bacteria associated with periodontal diseases.Green tea is a leading beverage in the Far East for thousands of years; it is regarded for a long time as a health product. Green tea is important source of polyphenol antioxidants. Polyphenols including epigallocatechin 3 gallate (EGCG) constitute the most interesting components in green tea leaves. Green tea has the potential to protect against various malignant, cardiovascular and metabolic diseases. There is a growing body of evidence pointing a beneficial role of green tea and its polyphenols in oral health. Green tea protects against bacterial induced dental caries. Tea polyphenols possess antiviral properties, believed to help in protection from influenza virus. Additionally, green tea polyphenols can abolish halitosis through modification of odorant sulphur components. Oral cavity oxidative stress and inflammation, consequent to cigarette smoking and cigarettes' deleterious compounds nicotine and acrolein, may be reduced in the presence of green tea polyphenols. Generally, green tea defends healthy cells from malignant transformation and locally has the ability to induce apoptosis in oral cancer cells. All together, there is an increasing interest in the health benefits of green tea in the field of oral health. Nonetheless, there is still a need for more clinical and biological studies to support guidelines for green tea intake as part of prevention and treatment of specific oral pathologies.

Cavity Prevention

Green tea controls bacteria and lowers the acidity of saliva and dental plaque, it may be a useful tool in preventing cavities. A recent study tested people before and after they gave their mouths a five-minute rinse with green tea.The test subjects had less bacteria and acid in their mouths, as well as reduced gum bleeding(2). Few researches had found that drinking green tea shows promise when it comes to preventing tooth decay.The effects of green tea extract on caries inhibition of hamsters and on acid resistance of human tooth enamel have been suggested by both *in vivo* and *in vitro* studies. The dialyzed tea solution in which the fluoride was removed almost completely also showed remarkable effects, similar to the original tea extract. The results obtained from this study suggested that fluoride in green tea may play a role in increasing the cariostatic action along with other components in tea. However, the action of fluoride does not seem to be so important because its concentration is very low. The effect of green tea on caries inhibition as well as on the increment of acid resistance appears to be more correlative with the nondialysable substances in tea.

Gum Health

Green tea's anti-inflammatory powers seem to help control periodontal (gum) diseases. German study found similar positive results in people who were asked to chew candies containing green-tea extracts.

Less Tooth Loss

It has made sense that a substance that helps prevent cavities and gum disease will help you keep yourteeth. Japanese research published in 2010 reported that men and women who drink green tea a day were more likely to hold on to their natural teeth(3).

Cancer Control

The antioxidants properties of green tea appear to protect against cellular damage and cancerous tumour growth. In University of Texas, green-tea extract was given to patients with precancerous lesions in their mouths, and it slowed the progression to oral cancer.Animal studies have also

found that tea compounds can inhibit cancer growth(4).The intake of green tea and its components such as catechin,had a preventive effect against cancer development.

Bad Breath

The University of British Columbia's Faculty of Dentistry measured the level of smelly compounds in people's mouths after they were given green-tea powder or another substance that supposedly helps with bad breath. Green tea outperformed mints, chewing gum and even parsley-seed oil in this study.

Role of Green Tea in Periodontitis

Gum disease, periodontal disease and periodontitis are different terms for the same condition.It occurs when the gums begin to separate from the teeth, leaving open spaces or pockets. A recently published study in the Journal of Periodontology, the official publication of the American Academy of Periodontology, has revealed benefit of drinking Green Tea(5). Author-dr. Yoshihiro Shimazaki of Kyushu University in Fukuok, Japan and his colleagues wanted to explore which is the impact of Green Tea consumption on periodontal health, with special emphasis on the link between periodontal and general health. Finally, they came to some interesting conclusions.Each cup of Green Tea daily resulted in a great decrease of the mentioned problems,as it dramatically reduced the incidence and stage of periodontal disease in males who followed it constantly(6).

Green Tea and its Polyphenols

Green tea catechins and polyphenols have a positive influence on the inflammatory reaction of periodontal structures. Streptococcus mutans plays an important role in causing dental caries. Leaves are rich in fluoride which is known to prevent dental caries. Besides fluoride, several green tea polyphenolshave preventative effects on dental caries(7).

Green Tea's Polyphenol Antioxidant

The green tea also possesses antiviral properties, which could help protect against the influenza virus that often enters through the mouth or nasal cavities (11). Additionally, green tea

polyphenols can be used as a natural remedy to treat bad breath. The sulfur compounds in green tea are thought to be responsible for its breath freshening effect (12). Green tea could help induce death in oral cancer cells. Polyphenols, antioxidants found in green tea, is believed to neutralize the risk of cancer caused by free radicals and can actually kill mouth cancer cells (15). Consuming this tea can prevent tooth decay. A new study shows drinking green tea or gargle use may inhibit the formation of dental plaque and prevent dental caries. Green tea has an antimicrobial effect on S. mutans, the bacteria responsible for tooth decay (13).

Oral Herbal Green Tea Brushing Salt

Olgani Green Tea Brushing Salts are a mild antibacterial and antifungal brushing salt formulation that can be used as an alternative to our powerful Original Salts while still providing an effective gum disease treatment (14). The main antioxidant in green tea, polyphenol, is a bioactive substance vital for maintaining, restoring and improving health in the human body (8).

Benefits of Green Tea in Oral Health

1. Protection against bacteria-induced dental caries

2. Prevent halitosis (bad breath) due to “modification of odorant sulfur components”

3. Prevent malignant formation of cells found in the mouth which could lead to oral cancer

Conclusion

Green tea extract may have numerous effects on periodontal pathogens and periodontal tissues. Greater the concentration of catechins better the health benefits. The consumption of green tea in comparison to other beverages may be widely recommended.

Halitosis – A Review

Boopana .K [1], Geo Mani[2]

Graduate Student [1], Senior Lecturer [2],Department of Pedodontics

Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstract

Halitosis is very common among any population, some believe that this distressing condition to be within a normal breath odour. Halitosis is common among the adult population group. Halitosis interferes with the social relationship and brought more awareness among the public. It becomes more necessary for the dentists for the proper understanding of oral as well as systemic factors that cause halitosis. Patient with halitosis may seek treatment from dental clinicians for their perceived oral malodour. Halitosis is not a disease but it is rather a symptom of underlying oral, systemic or psychological condition . psychosomatic halitosis is more difficult to diagnoise and manage , and patients with this condition are often mismanaged in that they get only treatments for genuine halitosis , even though they do not have a oral malodour. Management of halitosis include periodontal or restorative treatment or both, as well as simple treatment such as the introduction in oral hygiene, tongue cleaning and mouth rinsing. This article aims to address some misconceptions, and reviews on the cause, types, diagnosis, treatment, with the halitosis originating in the oral cavity

Key Words*: malodor, volatile sulphur compounds, oral cavity, oral hygiene , bacteria.*

Introduction:

Halitosis is the term which is used to describe any disagreeable odour in the air exhaled by the individual ,regardless of whether the odour originates in the oral cavity or elsewhere within the body[1]. Bad breath or halitosis is experienced by most of the people some time. It can simply be a morning breath but can also be persistent chronic condition which affects a person's everyday life and confidence. Halitosis emit a variety of volatile and non volatile molecules that are influenced by genetics , diet ,stress and disease. Halitosis causes embarrassment , may affect interpersonal social communication and it also has become an important market for the pharmacological and cosmetic industries. The prevalence of halitosis is reported to be as high as 50 percent[2]. Halitosis is not a disease but rather a symptom of underlying oral, systemic or psychological conditions [3]. Although the prevalence of halitosis and the incidence between male and female have been reported to be the same , women seem to seek more treatment more often than the men, in which some of the individuals who have halitosis but are totally unaware of it [4].

Causes of Halitosis :

The primary cause for halitosis is due to the release of odoriferous volatile sulphur compounds in the exhaled air. There are several things that may contribute to the bad breath , which include certain food , or food that are trapped between your teeth, gum disease, and tooth decay, dry mouth, tobacco products or a medical disorder. The basic that is present behind the origin of bad breath is the bacteria that live in the mouth if the individual which produce the volatile sulphur products . if there is enough amount of sulphur compounds there will b clinical bad breath5. Other reasons for bad breath are poor cleaning of teeth and tongue allowing bacteria to accumulate. It results from the breakdown or the decomposition of the bacteria left on the teeth and the tongue. This produces the VSC compounds which are exhaled while we are talking and breathing. The most common volatile sulphur compounds are the hydrogen sulphide which smells like a rotten egg, methyl mercaptan which smells like the animal faeces and the dimethyl sulphide smells like a cabbage6. Dry mouth called xerostomia can lead to the increase in the bacteria, as saliva usually has a protective function in the mouth. Morning breath and saliva flow

reduces , post nasal drips or sinus, smoking especially stale tobacco, intake of garlic and onion, dehydration[7].

Types of Halitosis :

One of the recent and frequently used classification is the halitosis id classified into three types the exogenous, endogenous and psychogenic halitosis. Halitosis is also classified as genuine halitosis, physiological halitosis, pathological halitosis, pseudo halitosis, halitophobia8

Genuine halitosis: presence of malodour that is beyond socially acceptable level .

Physiological halitosis: neither a specific disease nor a pathological condition that could cause halitosis is found, e.g . malodour from putrefactive processes within the oral cavity, temprorary halitosis due to the dietary factors9

Pathological halitosis

Oral: halitosis caused by disease, pathological condition or malfunction of oral tissues. Halitosis derived from the tongue coating, modified by pathological condition, e.g. periodontal disease, xerostomia.

Extra oral: malodour originates from nasal, paranasal sinuses, laryngeal regions, respiratory or upper digestive tract. Malodour originates from anywhere in the body whereby the odour is blood borne and emitted through the lungs. E.g diabetes mellitus, hepatic cirrhosis, uraemia and internal bleeding[10]

Pseudo halitosis: obvious maldour is nit perceived by others, although the patient complains of its existence. Condition is improved by counseling and simple oral hygiene measures[10].

Halitophobia: no evidence of any halitosis being present. After treatment for genuine halitosis or pseudo-halitosis, the patient fears that he/she has halitosis.

Diagnosis of Halitosis :

A complete dental examination is needed along with the medical and halitosis history, is essential to determine the cause of the halitosis. In subjects with the genuine halitosis, halitosis of oral origin has to be distinguished from halitosis of extraoral origin by comparing mouth breath, nasal breath and the lung air [11]. The first step in assessment is to determine if halitosis is present. This is more important as many of them are poor judges of their own breath odor. The assessment is usually based upon organoleptic assessment of exhaled air, namely the clinician sniffs the air exhaled from the mouth and nose and subjectively defines the presence or absence of malodor. Gas chromatography is considered by many to be the method of choice for the differentiation and quantifying the volatile sulfur compound and can also other classes of compounds like indole[12]. Examination of oral flora , for example using the BANA test or dark field microscopy, can be helpful, atleast for the patient education. Assay for the major glysocidic enzyme in the saliva, which deglycosylates the oral mucins, leading to their subsequent proteolysis and putrefaction , may also be very useful[13].

Treatment of Halitosis :

Treatment for physiological halitosis: explanation of halitosis and instructions for oral hygiene(support and reinforcement of a patient’s own self-care for further improvement of their oral hygiene[14]

Treatment pathological halitosis: oral and extra oral : explanation of halitosis and instructions for oral hygiene and the support and reinforcement of a patient’s own self care for further improvement of their oral hygiene and oral prophylaxis , professional cleaning and treatment for oral diseases, especially periodontal diseases[15] . Treatment for pseudo halitosis: explanation of halitosis and the instructions for the oral hygiene for the support and the reinforcement of a patient’s own self-care for further improvement of their oral hygiene. Explanation of examination data, further professional instruction, education and reassurance [16].Treatment for halitophobia: explanation of halitosis and the instructions for the oral hygiene for the support and

the reinforcement of a patient's own self – care for further improvement of their oral hygiene. Referral to a clinical psychologist, psychiatrist or other psychological specialist[17]

Control and Prevention of Halitosis :

Control and prevention include active periodontal therapy either at our office or reffered to a specialist. Treat any existing decayed tooth and the drymouth issues. Eliminate any tobacco use habits. Maintain optimal oral care at home. Use a carbamide peroxide gel in custom made halitosis trays[18,19] .All patient need to do the following : brush with oxyfresh tooth paste regularly as well as your fluoride containing toothpaste and brush twice a day. Floss the teeth atleast one daily. Brush the teeth twice a day for atleast 1-2 minutes with a small drop of the oxyfresh tooth paste. Use of oxyfresh mouthrinse at least twice a day. Avoiding the alcohol containing mouth wash and use of ACT fluoride mouth wash that are alcohol free and helps in the prevention of tooth decay and halitosis20. For the person who have halitosis all day custom made halitosis trays with carbamide peroxide gel half an hour in the evening. For the persons who bad breath in the morning they can wear custom made halitosis trays with carmbamide peroxide at night when you sleep. For the patients who have evening breath they can wear custom made halitosis with carbamide peroxide about 3 hours before the onset of when you feel the bad breath occurs. Wear it for half an hour[21]. The other general measures that are to adopted is having a scale and polish to remove the hard and soft deposits and also tongue brushing. Regular checkups ,smoking cessation , reduce alcohol consumption , reduce the intake of food such as garlic and onion and a balanced healthy diet[22].

Conclusion:

The patients seek a lot of therapy from the dentist than from the physicians. It is therefore very crucial for the dentists to have an understanding of all types of halitosis , especially those that arise from the oral cavity. Several misconception about halitosis need to put a step side . the

available evidences indicates that the volatile sulpur compounds are nit just odoiferous , but that some of them are deleterious to the periodontal health. Therefore treatment of halitosis can no longer be considered as just a cosmetic therapy.

Health Eating Index for Children –A Review

NirishaSriram[1],R.Navaneethan[2],G.Deepa[3],
Graduate Student[1],Reader[2], Department of Orthodontics, Professor[3], Department of Pedodontics[3],
Saveetha Dental College,Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstract

Children are more prone to various diseases as their immune system is still in development. A good immune system can be builtonly when the child is at the best of health and good health in turn is dependent on a healthy diet and good exercise. A healthy diet means a good intake of food which has all the essential nutrients in the right amounts. The diet would vary slightly with individuals depending on their day to day activity. It also varies with the age and gender of the individual. Thus the quantity and the quality of food that is consumed are of most importance. When we see the health of the individuals in a community, it becomes important to quantify as to what constitutes a healthy diet both qualitatively as well as quantitatively. This quantification can be done with the help of Indices that measure the type and quantity of food consumed. Various committees have proposed different diet eating indices to standardize the type of food to be consumed. The indices serve not only to know the diet status of the individuals in a community but also serve as a guide to the individuals regarding their daily dietary requirements.

***Key words*:** *Diet indices, Health eating Index, Food Pyramid, Children,Healthy diet.*

Introduction

A good healthy smile boosts the self-confidence of an individual weather it is an adult or child. A good smile is dependent on strong, healthy teeth surrounded by a healthy periodontium which in turn depends on a healthy diet. The nutrition deficiency manifestations in the oral cavity serve as a testament to the importance of a healthy diet. This is where the role of indices comes in as they assess and quantify the nutritional status of various food products. These dietary indices calculate the food habits of an individual and the amount of food consumed which offers a brief knowledge of the person's health in relation to their diet.

Different diet quality assessment indices assign scores which indicate the health status of an individual based on the consumption of these food items[1]. At present two methods are used to assess the nutritional quality of the food items namely priori which gives scores to the food items based on food guides and a posteriori analysis which uses statistics to find the diet of a particular population[2]. The four most commonly used indices used are a) Health eating index, b) Diet quality index, c) Mediterranean diet score and d) Overall nutritional quality index[3]. Of the four Indices, the Health Eating Index is the most widely used and it has been modified in different countries to estimate the diet quality in the respective populations.

Health Eating Index (Hei)

It is a measure of diet quality that is in line with the Dietary Guidelines for Americans (DGA), which is the basis of nutrition policy for the US government. The health eating index

is revised every 5 years. The first HEI was introduced in 1995(Table 1). The HEI 1995 included 10 components with each component being given a score of 0-10. Of the 10 components, 5 components were for the type of foods that are present in the original food pyramid, 4 components for the five major food types that should be consumed in moderation or in limited amounts like fats, sodium etc. and 1 component measures the variety in the diet. The criteria for scoring were also clearly defined based on the number of servings, energy obtained from fats etc. An overall score of 80 and above was suggestive of a healthy diet, while a score between 80-50 was considered to require improvement while a score of less than 50 was considered poor. Further the scoring was categorised based on age and gender so as to take into considerations the different requirements at each age group and for each gender[4]. The HEI of American children estimated during from 1994 to 1996 showed that the children were in the category that needed improvement as the scores varied between 66.4 (lowest score over the years) to 74.4 (highest score over the years)[5]. The scores for children in 1999-2000 period ranged from 66 to 75.7 which was still in the need improvements group.[6]

Table 1: HEI-1995

Component	Score Ranges	Criteria for Maximum Score of 10	Criteria for Minimum Score of 0
Grain consumption	0 to 10	6 - 11 servings	0 servings
Vegetable consumption	0 to 10	3 - 5 servings	0 servings
Fruit consumption	0 to 10	2 - 4 servings	0 servings
Milk consumption	0 to 10	2 - 3 servings	0 servings
Meat consumption	0 to 10	2 - 3 servings	0 servings
Total fat intake	0 to 10	30% or less energy from fat	45% or more energy from fat
Saturated fat intake	0 to 10	Less than 10% energy from saturated fat	15% or more energy from saturated fat

Cholesterol intake	0 to 10	300 mg or less	450 mg or more
Sodium intake	0 to 10	2400 mg or less	4800 mg or more
Food variety	0 to 10	8 or more different items in a day	3 or fewer different items in a day

The HEI was updated over the years and in 2005 and very an updated version, HEI-2005 (Table 2) was created. The HEI 2005 was based on food patterns on the MyPyramid[7] and had 12 components. The various components are classified into two groups. The first was the "adequacy components" which contained all the essential food groups namely Total fruit, Whole Fruit, Total Vegetables, Dark green & Orange vegetables & Legumes, Total grains, Whole Grains, Milk, Meat and Beans and Oils. The second group was the moderation group which contained all the foods that have to be consumed in moderation namely the saturated fat, Sodium and Calories from Solid Fat, Alcohol and Added Sugars (SoFAAS). The first six components of the adequacy group had a scoring of 0-5 while milk, Meat & Beans and Oil had a scoring of 0-10 each. Among the moderation group, saturated fat and sodium had a scoring of 0-10 each while SoFAAS had a scoring of 0-20. The total score was again 100. The amount of food intake was estimated on a density basis that is the amount per 1000 calories intake[8]. The average HEI-2005 score for children aged between 2 to 17 years of age was 55.9 during 2003-2004[9]. This indicated that there required a large improvement in the diet patterns in the American children.

Table 2:HEI-2005

Component	Maximum points	Standard for maximum score	Standard for minimum score of zero
Total Fruit (includes 100% juice)	5	≥0.8 cup equiv. per 1,000 kcal	No Fruit

Whole Fruit (not juice)	5	≥0.4 cup equiv. per 1,000 kcal	No Whole Fruit
Total Vegetables	5	≥1.1 cup equiv. per 1,000 kcal	No Vegetables
Dark Green and Orange Vegetables and Legumes	5	≥0.4 cup equiv. per 1,000 kcal	No Dark Green or Orange Vegetables or Legumes
Total Grains	5	≥3.0 oz equiv. per 1,000 kcal	No Grains
Whole Grains	5	≥1.5 oz equiv. per 1,000 kcal	No Whole Grains
Milk	10	≥1.3 cup equiv. per 1,000 kcal	No Milk
Meat and Beans	10	≥2.5 oz equiv. per 1,000 kcal	No Meat or Beans
Oils	10	≥12 grams equiv. per 1,000 kcal	No Oil
Saturated Fat	10	≤7% of energy[5]	≥15% of energy
Sodium	10	≤0.7 gram per 1,000 kcal[5]	≥2.0 grams per 1,000 kcal
Calories from Solid Fats, Alcoholic Beverages, and Added Sugars (SoFAAS)	20	≤20% of energy	≥50% of energy

The HEI-2005 was later updated to HEI-2010 (Table 3) and the HEI 2010 had nearly the same components of the HEI 2005 with slight modifications.Like the HEI 2005, the new version has an “Adequacy group” and a “Moderation group”. The Adequacy group in HEI 2010 consists of the following components a) Total Fruit, b)Whole Fruit, c)Total Vegetables, d)greens and beans, e)Whole Grains, f)Dairy g)Total Protein foods, h) Seafood and Plant proteins and i) fatty acids. The scoring was between 0-5 for total fruit, whole fruit, total vegetables, greens and beans, total protein foods and seafood and plant proteins while dairy, whole grains and fatty acids have a scoring of 0-10 each. The moderation group consisted of Refined Grains, Sodium and Empty Calories. Refined grains and sodium had a scoring of 0-10 each while ‘empty calories’ was scored 0-20[10].

Table 3: HEI 2010

Component	Maximum points	Standard for maximum score	Standard for minimum score of zero
Adequacy:			
Total Fruit	5	≥0.8 cup equiv. per 1,000 kcal	No Fruit
Whole Fruit	5	≥0.4 cup equiv. per 1,000 kcal	No Whole Fruit
Total Vegetables	5	≥1.1 cup equiv. per 1,000 kcal	No Vegetables
Greens and Beans	5	≥0.2 cup equiv. per 1,000 kcal	No Dark Green Vegetables or Beans and Peas
Whole Grains	10	≥1.5 oz equiv. per 1,000 kcal	No Whole Grains
Dairy	10	≥1.3 cup equiv. per 1,000 kcal	No Dairy
Total Protein Foods	5	≥2.5 oz equiv. per 1,000 kcal	No Protein Foods
Seafood and Plant Proteins	5	≥0.8 oz equiv. per 1,000 kcal	No Seafood or Plant Proteins
Fatty Acids	10	(PUFAs + MUFAs)/SFAs ≥2.5	(PUFAs + MUFAs)/SFAs ≤1.2
Moderation:			
Refined Grains	10	≤1.8 oz equiv. per 1,000 kcal	≥4.3 oz equiv. per 1,000 kcal
Sodium	10	≤1.1 gram per 1,000 kcal	≥2.0 grams per 1,000 kcal
Empty Calories	20	≤19% of energy	≥50% of energy

Table 4:HEI 2015

Component	Maximum points	Standard for maximum score	Standard for minimum score of zero

Adequacy:			
Total Fruits	5	≥0.8 cup equiv. per 1,000 kcal	No Fruit
Whole Fruits	5	≥0.4 cup equiv. per 1,000 kcal	No Whole Fruit
Total Vegetables	5	≥1.1 cup equiv. per 1,000 kcal	No Vegetables
Greens and Beans	5	≥0.2 cup equiv. per 1,000 kcal	No Dark Green Vegetables or Legumes
Whole Grains	10	≥1.5 oz equiv. per 1,000 kcal	No Whole Grains
Dairy[5]	10	≥1.3 cup equiv. per 1,000 kcal	No Dairy
Total Protein Foods	5	≥2.5 oz equiv. per 1,000 kcal	No Protein Foods
Seafood and Plant Proteins	5	≥0.8 oz equiv. per 1,000 kcal	No Seafood or Plant Proteins
Fatty Acids	10	(PUFAs + MUFAs)/SFAs ≥2.5	(PUFAs + MUFAs)/SFAs ≤1.2
Moderation:			
Refined Grains	10	≤1.8 oz equiv. per 1,000 kcal	≥4.3 oz equiv. per 1,000 kcal
Sodium	10	≤1.1 gram per 1,000 kcal	≥2.0 grams per 1,000 kcal
Added Sugars	10	≤6.5% of energy	≥26% of energy
Saturated Fats	10	≤8% of energy	≥16% of energy

The next updated version HEI 2015 (Table 4), is yet to be published but based on the dietary guidelines 2015 by the US government, it is expected to retain all the components of the HEI 2010. The only change expected is the extra calories component being split into two namely a) added sugars and b) saturated fats with each component having a scoring of 0-10[11]. The HEI is the most commonly used dietary index and it has been used to estimate the quality of various diets[12-15], in different population samples and had also been used to associate diet with nutritional and other diseases[16-18].

The HEI-2010 scores for children ranged from 43.59 to 52.11, which was lower than the minimum score of 80[19]. The scores were closer to the “poor” category (51 and below). This showed the dire need to improve on the diet requirement in children. Similar findings have been found among pre-schoolers in Greece[20]with most children (80%) scoring below 50 while only 0.4% children were in the good category. Fernanda Rauber et al[21] studied thediet

quality of children of the low economic status using an adapted version of the HEI and got mean scores of 65.7 for children of 3to 4 years of age and a score of 65 for children aged 7 to 8 years. These values, though higher than those of the American and Greece children, cannot be compared to them as the HEI index used was modified for the Brazilian diet. Another Brazilian studyused HEI to standardise the study and found that rice fortified with micronutrients improved the folic acid, thiamine, haemoglobin concentrations in the blood. This study suggested that using fortified rice in school programs could improve the intake of micronutrients[22]. Another American study showed that the diet of children with autism did not vary much from the diet of normal children as measured by the HEI[23].Angelopoulos et al[24] found that majority (84.5%) of the participants fell under the HEI score of 50-80 which was the 'needs Improvement' category while 12 % had a 'poor diet' and only 3.5% children had a 'good diet'.

All the above studies show that there is a dire need for improvement in the diet of children, irrespective of which country they belong to. There is an overall deficiency in children who have of a well-balanced diet. And when such deficiency is noted in children of developed countries, the situation of the children in the developing and the underdeveloped world would paint a scary picture.

Conclusion

To conclude, indices help in correlating diet and the risk of nutritional and systemic diseases which indirectly affect the overall status of the oral cavity. There is a more need of calculation of these indices in children as they are more prone to have an irregular diet which might lead to nutritional deficiency. In such conditions the teeth of the children are equally affected as that of the general health. Moreover thechances of deformation are more common in primary teeth which will interrupt the growth of permanent teeth and its function. Having a hale and healthy diet will indirectly result in a good smile. For a healthy life appropriate proportion of all types of food is essential which is calculated with the help of dietary indices.

Abstract

Heart rate variability (HRV) is a reliable reflection of the many physiological factors modulating the normal rhythm of the heart. In fact, they provide a powerful means of interplay between the sympathetic and parasympathetic nervous systems. It shows that the structure generating the signal is not only simply linear, but also involves nonlinear contributions. Heart rate (HR) is a nonstationary signal, and the variations in that may contain indicators of current disease, or warning about any impending cardiac diseases. This indicator may be always present or may occur at certain intervals of the day. HR variation analysis has become a popular non-invasive tool for assessing the activities of the autonomic nervous system. Heart rate variability (HRV) is widely used for quantifying neural cardiac control, and low variability is particularly predictive of death in patients after myocardial infarction.

Key Words:*Cardiac Death, Epinephrine andnor Epinephrine,Heart Rate Variability,Myocardial Infarction (MI), Vagus Nerve.*

Introduction

Heart rate, measured as beat to beat intervals, which is not constant and varies in time. Heart rate variability (HRV), the variation over time of the period between consecutive heartbeats, is predominantly dependent on the extrinsic regulation of the heart rate (HR). HRV is the ability of heart to adapt to changing circumstances by detecting and quickly responding to unpredictable stimuli. (1) Heart rate variability provides a non-invasive and indirect measurement of the autonomic control of the heart. A high variability in heart rate implies a healthy individual with a well-functioning autonomic nervous system. A low HRV indicates an abnormal autonomic system. Abnormalities in HRV have been reported in a variety of medical conditions including myocardial infarction, diabetes, the metabolic syndrome, end stage renal disease, chronic liver disease, hypoxic lung disease, and chronic heart failure and HIV infection. (2) HRVcan beanalysed with the variations in normal consecutive heart beats or R-R intervals.Analysis of Heart rate variability is very important and gives the overall cardiac health and state of the autonomic nervous system (ANS) which is responsible for regulating cardiac functions. The normal variability in HR is due to autonomic neural regulation of the heart and the circulatory system. (3) The balancing actions of sympathetic nervous system and parasympathetic nervous system controls the HR. The degree of variability in the heart rate provides information about the functioning of the nervous system on the heart rate and the heart's ability to respond.(4)

The amount of HR fluctuations around the mean HR can be used as cardio respiratory control system. It is an important tool to investigate the sympathetic and parasympathetic function of ANS. It also gives information regarding the sympathetic-parasympathetic autonomic balance and about the risk for sudden cardiac death (SCS).(5) It is influenced by various physiological factor including age, postural changes, and time of day. Pathological conditions such as congestive heart, diabetic neuropathy and coronary heart disease also are associated with alterations in heart rate variability. Heart rate and rhythm are under the control of the autonomic nervous system. (6) The parasympathetic influence on heart rate is regulated via release of acetylcholine by the Vagus nerve. Muscarinic acetylcholine receptors respond to this release mostly by an increasing the K^{2+} conductance in cell membrane. The sympathetic influence on heart rate is mediated by epinephrine and norepinephrine. Sympathetic stimulation, occurring due to stress, exercise and heart disease, increases the heart rate by increasing the firing rate of pacemaker cells in the heart's sino atrial node. (7)

Parasympathetic activity, results from the functions of internal organs, trauma, and the allergic reactions, decreases the firing rate of pacemaker cells and the HR, providing a regulatory balance in physiological autonomic function. Rhythms from sympathetic and parasympathetic activity contribute separately for the modulation of heart rate (RR) intervals of the QRS complex in the electrocardiogram (ECG)at distinct frequencies.[8] The RR interval variations present during resting conditions represent beatbybeat variations in cardiac autonomic inputs.

Heart Rate Variability in Myocardial Infarction

A reduction in parasympathetic cardiac control and predominance of sympathetic activity are seen in patients with acute myocardial infarction.HR variability in AMI was related to age, as older patients tended to have lower HR variability values than younger AMI patients. (9) It was found that low HR variability at an early stage of AMI is significantly associated with early mortality and major complications. It was shown that, the HRV decreases withthe recent MI. Depressed HRV after Myocardial infarction indicates decrease in vagal activity directed to the heart. (10) HRV in patients surviving an acute MI reveal a reduction in total and in the individual power of spectral components.Clinical depression is associated with an increased risk for mortality in patients with a recent myocardial infarction (MI). (11)

Decreased HRV in Chronic Obstructive Pulmonary Disease

Patients with COPD are less able to respond to sympathetic and parasympathetic stimuli, in other words their control system are working at saturation level, so they could not have the normal range of variation and even opposite stimuli cannot modify their autonomic pattern. In patients with heart failure, the autonomic system is driven by an exaggerated sympathetic tone.(12) Similarly, patients with COPD, have altered sympatho-adrenal response to chronic moderate bronchoconstriction. One possible reason for the lack of RR variability in patients withCOPD might be a light constant compensatory sympathetic activity in response to an increase in airwayresistance. Larsson et al. suggested that this impaired sympatho-adrenal response is not from an alteration of plasma noradrenalin concentrations. Another possibility is that sympathetic outflow response may be normal, but that there could be a block to the

action circulating catecholamine, due to receptor down regulation. The down regulation could be due in part to long-term therapy with theophylline or d-agonists and in part to increased circulating endogenous catecholamine.(14) Usually in patients with COPD an imbalance is seen in autonomic nervous system activity. This is apparently driven at rest by an increase in vagal activity and through the lack of responses to sympathetic stimulation. This altered balance could contribute to the airways obstruction in COPD.(15)

Heart Rate Variability in Chronic Heart Failure

Despite recent advancement in management of chronic heart failure, mortality remains high and death often occurs suddenly. Identification of patients with chronic heart failure at risk for sudden death remains difficult. Low heart rate variability (HRV) is an indicator of increased risk of sudden cardiac death after myocardial infarction and in patients with chronic heart failure.(16) Regular physical activity could modify the risk of sudden cardiac death. Chronic heart failure is characterised by significant autonomic dysfunction consisting of sympathetic activation, parasympathetic withdrawal, and peripheral organ unresponsiveness.

Chronic heart failure (CHF) is also associated with major abnormalities of autonomic cardiovascular control. Among several prognostic factors, the extent of neurohormonal activation (17),particularly plasma norepinephrine levels, are found to be independently related to survival ofpatients with heart failure. Profound abnormalities in autonomic control, characterized by generalized sympathetic over activity and parasympathetic withdrawal, are a typical feature of neuroendocrine activation in heart failure.(18) It is also expected that increased sympathetic activity would be accompanied by a relative predominance of Low frequency(LF)oscillations –domain analysis of HRV.However, both increased and reducedLF power were found to be associated with an increased risk of cardiac death. In the present studies it has been stated that reduced LF power (particularly duringcontrolled breathing) independently predicted sudden, presumably arrhythmic death in a multivariate model testing the majority of the recognized pathological determinants of CHF in both the derivation and validation series. (19) In CHF patients, abnormal breathing patternsplays a confounding role thatis abolished by controlled respirationor O2administration. Moreover the absence of a sustained abnormal breathing pattern alters the regularity of tidal volume (i.e. irregular) in CHF patients, thus affecting the HRV assessment. (20) The main finding isthat in patients

with chronic heart failure, heart rate variability, as assessed by time domain and spectralanalysis, has prognostic value not only for the identification of patients at increased risk for mortality but, most importantly, also for sudden death. Among time domain indexes, a lower SDNN is a significant and independent predictor of all-cause mortality and of progressive heart failure death. Among spectral measures, reduced power within the low frequency band during daytime is a significant and independent predictor of sudden death risk. Hence reduced heart rate variability has been observed consistently in patients with cardiac failure.(21)

Effect of Exercise Training on Heart Rate Variability

There are two types of exercise training: Resistance & dynamic exercise training. The adaptation of cardiovascular system to resistance exercise training is different from adaptation to dynamic exercise training. Heart muscle shows signs of concentric hypertrophy in resistance training, whereas in dynamic training the adaptation is characterised by increase on heart cavities & limited heart wall thickening.(22) In such situation, hypertrophy is considered as eccentric. Hence dynamic training is considered to be more efficient than resistance training on the decrease of heart rate & systolic blood pressure at rest and also on the increase of stroke volume at rest and during exercise. Thus it is possible that various types of exercises influence the HRV in a different manner. Hence Regular physical exercises can reduce the risk of sudden cardiac death. (23)

Effect of HRV in Coronary Artery Disease

Autonomic nervous controls cardiovascular system and has a distinct circadian rhythm,and this may be animportant mechanism underlying the diurnal distribution of cardiac events such as myocardial ischemia, myocardial infarction, and cardiac death.(24) Analysis of heart rate variability (HRV) in the frequency domain is a novel method of studying cardiovascular neural regulation. Decrease of HRV is frequently associated with coronary artery disease (CAD). Theamplitude of circadian rhythm of the HF component of HRV was blunt in the patients with CAD compared with healthy ones suggesting that the vagal responses to endogenous or exogenous stimuli are reduced in CAD.(25)The circadian rhythm of

normalized power of the LF component of HRV was also blunted in the patients with CAD, suggesting that the diurnal fluctuation of both vagal and sympathetic activity is altered in CAD. There was less variation in heart rate during deep breathing in patients with coronary artery disease. Heart rate variation during deep breathing was not sufficiently related to age in patients with CAD. (26)

Autonomic nervous system imbalance in the form of reduced vagal and enhanced sympathetic activity is supposed to be the basis of diminished heart rate variability in coronary artery disease patients. Previous literature suggests that distorted vagal nerve endings and enhanced release of norepinephrine from sympathetic nerve fibers is the underlying mechanism of altered activity of autonomic nervous system. Preceding myocardial ischemiacauses alteration in distribution ofautonomic nerve fibers. Heterogeneity of autonomic innervation leads to augmented sympathetic influence and reduce vagal intonation in coronary artery disease patients leading to reduced heart rate variability.(27)

Chronic myocardial infarction (MI) causes destruction of the ventricular neural receptors, which results in altered autonomic regulation and ageing has significant effects on vagal heart rate control. One of the recent study done in patients with CAD, but without a prior MI, indicated that the 24-h average frequency domain measures of HRV were not significantly reduced in CAD patients compared with age-matched healthy subjects.(28)Healthy subjects have a distinct circadian rhythm of HRV, while this rhythm seems to be blunted in CAD patients, and their autonomic responses to the sleep-awake rhythm are abnormal, suggesting that the central modulation of the autonomic control of the heart rate is altered in CAD. Similar abnormalities in the circadian rhythm of HRV have been observed in hypertensive patients. (29)

Low HRV is always associated with an increased risk of overall mortality in post infarction patients. According to the results of study done by Farrell et al. and Bigger et al. (30) suggested that impaired HRV was particularly related to an increased risk of arrhythmic sudden death. Reductions in the VLF and LF spectral components of HRV seem to be more closely related to an increased risk of sudden arrhythmic death than the HF component. On the other hand, Bigger et al. also reported that reduced HRV also predicts cardiac mortality in patients with remote MI and Rich et al.(31) showed in a small population with CAD, but

without a prior MI, that reduced HRV increased significantly the risk of cardiac mortality. The incidence of arrhythmic cardiac death is relatively low in these patient populations, suggesting that low HRV may also be associated with the risk of non-arrhythmic cardiac death, such as acute coronary events or progressive heart failure.(32)

Depressed Mood and Herat Rate Variability

Depression is an independent risk factor for mortality after MI Parasympathetic tone is an important factor in the development of cardiac arrhythmia.(33) Among healthy individuals, parasympathetic tone helps to prevent ventricular arrhythmias by maintaining the electrical stability of the heart. When parasympathetic tone is decreased, cardiac arrhythmias are more likely to occur (34). Although stress decreases parasympathetic tone, under normal conditions enough parasympathetic tone remains during stress to prevent ventricular arrhythmias. Neural fibres are damaged due to MI, such as when the autonomic influences on heart on compromised, extreme stress may provoke lethal arrhythmias and sudden death.

Power Spectral Analysis of HRV Identifies Congestive Heart Failure

Autonomic dysfunction seems to be involved in the progression and prognosis of severe congestive heart failure. Power spectrum analysis of heart rate variability in congestive heart failure may identify patients with a more pronounced sympathovagal imbalance and, as a consequence, could be at major risk of the disease worsening and have a poorer prognosis. Heart rate variability was reduced in patients with congestive heart failure. Two spectral patterns were identified .The first was characterised bya predominant LF component and a reduced HF component, suggesting sympathetic predominance and parasympathetic withdrawal. In the second a major reduction intotal power, an undetectable LF componentand a low amplitude HF peak. Patients with undetectable LF were more severely affected and with depressed left ventricular function and a higher degree of sympathoexcitation, reflected by the higher plasma noradrenalinconcentrations. It was also suggested that parasympathetic activity is inversely related and that sympathetic activity and noradrenaline concentrations are directly related to the severity of heart failure and prognosis.

Therapeutic Interventions and Heart Rate Variability

It is always important to find therapeutic methods which would improve heart rate variability. Beta-blocking therapy has been shown to increase HRV both in healthy subjects and in patients with Coronary artery disease.(36)This improvement in HRV has been suggested to contribute to the protective effects of beta-blockade in ischaemic heart disease. The exact reason is unknown for increase in the measures of HRV after beta-blockade but itis merely due to the decrease of heart rate or increases the vagal modulation of heart rate. Scopolamine, which is a vagotonic agent, has also been shown to increase the respiratory component of HRV. Angiotensin-converting enzyme inhibitors may also improve the HRVand physical training has been reported to increase it. Despite these potential methods for improving HRV, there are other pharmacological or other methods to improve HRV and prevent cardiovascular morbidity or mortality.

Effect of Beta Blockers and Other Cardioactive Drugs on Heart Rate Variability

Previous studies showed that beta-blocker therapy augmented heart rate variability in patients with coronary artery disease. Thusbetablockers significantly increased high frequency power spectra and the rootmean square of the differences of successive RR intervals. Power in “the low frequency band tend to be higher with beta blockers, but the difference relative to placebo was not significant. The standard deviation of normal RR intervals and very low and ultra- low frequency power, which are independent predictors of mortality in patients after acute myocardial infarctionwere also significantly augmented by betablockers.

Mechanisms of Modifying Heart Rate Variability

Use of beta blockers resulted in significant argumentation of high frequency power and the root mean square successive difference of normal RR intervals, which is considered to reflect parasympathetic activity. However, reduction of the average heart rate itself (i.e., increase in the mean RR intervals) might result in increase in both the time and frequency domain measures of RR interval variability. Thus beta blocker induced changes of variability indexes may be due to increased vagal tone, reduced sympathetic beta receptors stimulation or a

combination of the two. The equal effects of metoprolol and atenolol on heart rate and high frequency power suggests that these two beta blockers with different lipophilicity elicited similar changes of cardiac vagal sympathetic balance.

Conclusion

Heart rate variability has proved to be a valuable tool to investigate the sympathetic and parasympathetic function of the ANS.HRV analysis has become important in cardiology , because its measurements are easy to perform,non-invasiveand provide prognostic information on patients with heart disease.

Abstract

Hibiscus rosasinensis Linn. is certain to emerge in the near future as a major player in the growing field of herbal health supplements and medicines both in daily self-care and in professionally managed health care system.The principal constituents of Hibiscus rosasinensis Linn. areflvones. Flvones contain quercetin-3-diglucoside, quercetin-3,7-diglucoside, cyaniding-3,5-diglucoside, quercetin-3-sophorotrioside, kaempferol-3xylosylglucoside, cyaniding-3-sophoroside-5-glucoside and other constituent are cyclopeptide alkaloid, cyanidin chloride, hentriacontane, riboflavin, ascorbic acid, thiamine, taraxeryl acetate, ß-sitosterol , cyclicacidssterculic and malvalic acids. All the parts of Hibiscus rosasinensis Linn and chemical constituents are used as anti-tumor, antifertility, antiovultory, antiimplantation, anti-inflammatory, analgesic, antiestrogenic, antipyretic, antispasmodic, antiviral, antifungal, antibacterial, hypoglycaemic, spasmolytic, CNS depressant, hypotensive and juvenoid activity. This article compile all the information related to Hibiscus rosasinensis Linn.

Key Words:*Hibiscus rosasinensis, drugs, anti-inflammatory, juvenoid activity, antioxidants*

Introduction

Plants have been a source of medicine from time immemorialand a number of modern drugs have been isolated from natural sources, many based on their use in traditional medicines.over the years, world health organization has advocated traditional medicines as safe remedies for aliments of both microbial and non microbial origins[1].Hibiscus rosa-sinensis, known colloquially as the chinese hibiscus, china rose and shoe flower, is an evergreen flowering shrub native to east asia.it is widely grown as an ornamental plant throughout the tropics and subtropics. The flowers are large, generally red in the original varieties, and firm, but generally lack any scent. Also many colors are available in a single, double or multi-shades including white, yellow, orange, red, pink, salmon, purple, etc. Hibiscus rosa-sinensis, is the national flower of malaysia. The leaves are alternate, simple, ovate to lanceolate, often with a toothed or lobed margin. The flowers are large, conspicuous, trumpet-shaped, with five or more petals. The fruit is a dry five-lobed

capsule, containing several seeds in each lobe, which are released when the capsule dehisces (splits open) at maturity. Uses: to induce abortion, ease menstrual cramps and to help in childbirth. To treat headaches. A preparation from the leaves is used to treat postpartum relapse sickness, to treat boils, sores and inflammations. Good for hairs. Hibiscus flowers are reported to possess anti-fertility property by ancient ayurvedic texts. It is also used for the worship of devi and especially the red variety takes an important part in tantra. Hibiscus is a popular herbal plant which belongs to the family malvaceae and has high medicinal value.its 250 species are widely distributed in tropical and subtropical regions and are reported to posses various medicinal properties including antitumor, antihypertensive, antioxidant and anti ammonemic.[1–4] the extracts from different parts of the plant are used as emmenagogues,abortifacients, contraceptives and labour inducers. It has various pharmacological actions like ameliorative potential,anti fertility activity, anti inflammatory activity, antidiabetic activity, anti fungal activity and cardio protective functions. A literature review is done to study these properties of hibiscus plant.

Common Names

China rose, jaba, jasum ,sadaphool , sambathoochedi , jasunt , mandasa (5).

Chemical Constituents

Composition: various parts of the plant contain a number of chemical constituents, that are of major pharmacological importance. The stem and leaves contain stigmasterol, β-sitosterol, taraxeryl acetate and three other cyclopropane compounds along with their derivatives. Flowers are composed of flavonoids, diglucoside, and vitamins like thiamine, riboflavin, ascorbic acid and niacin (ghani, 2003). Quercetin-3-diglucoside, 3, 7- diglucoside, cyanidin-3-sophoroside-5-glucoside and cyaniding-3,5-glucoside have been isolated from the bright yellow flowers of this plant. Along with these compounds, kaemferol-3-xylosyl glucoside has been isolated from white ovary flowers (kumar, 2012). Five new phyto constituents have been isolated from the flowers of hibiscus rosasinensis. These were found to be n-docosane, n-entacos-4-en-3-one-18, 23-diol and henicos-11-ene-8-one, stigmast-5-ene-3 β, 4a- diol, stigmast-5-ene-3 β-benzyloxy-12 β-ol (kasture, 2000; siddiqui, 2006). The total anthocyanin composition was reported to be 165 mg/kg with about 6% reduction due to fermentation. Tannin content is reported as 11.8g/kg. Ascorbic acid and total polyphenol composition is established as 478 mg /kg and 14.4 mg/g, respectively. The phytochemical screening reveals the presence of alkaloids and saponins. The antioxidant activity of the extract is significantly lower (ec50 = 43.9 µg/ml) compared to ascorbic acid (e 50 = 3.3 µg/ml) (mak, 2013). Total phenolic content in hibiscus rosasinensis was reported to be 48.4±1.03mg catechol equivalent/g and the total flavonoid content was established as 24.26 ± 1.1mg catechol equivalent/g (shirwaikar, 2005).leaves and stems contain β-sitosterol, stigmasterol, taraxeryl acetate and three cyclopropane compounds and their derivatives. Flowers contain cyanidindiglucoside, flavonoids and vitamins, thiamine, riboflavin, niacin

and ascorbic acid (ghani, 2003). Quercetin-3-diglucoside, 3,7-diglucoside, cyanidin3,5-diglucoside and cyanidin-3-sophoroside-5glucoside have been isolated from deep yellow flowers.kaempferol-3xylosylglucoside has been isolated from ovary white flowers (rastogi&mehrotra, 1993)(5).

Ecology of Hibiscus

The genus 'hibiscus' includes both annual and perennial herbaceous plants, woody shrubs and small trees. The leaves are generally simple, ovate to lanceolate, having a lobed or toothed margin. The flowers are generally big, conspicuous and trumpet shaped having five or more petals. They are coloured flowers ranging from white to purple, red, pink and sometimes yellow. The petals are very broad ranging from 4 to 15cm. Flowers have nectarines, that are composed of several tightly packed glandular hairs, and are generally positioned at the sepals. The fruit is a capsule made up of dry five-lobes. It contains numerous seeds in each of its lobes, which then are released at the time of maturation, when the capsule splits open (alarcon, 2007; ames, 2013). Hibiscus plants are a source of beneficial ecological, aesthetic, culinary and medicinal values. Ecologically, the large flowers give nectar to large pollinators such as hummingbirds. Many insects use these flowers as a source of food. It is also well known for its aesthetic values. There are a wide range of varieties of this plant. They can be of many colours such as orange, red, white and pink having a single or double set of petals. Being large and trumpet shaped, the hibiscus is often used as a garden plant as well as a potted plant. They issn: 0974-2115 www.jchps.com journal of chemical and pharmaceutical sciences october-december 2015 971 jcps volume 8 issue 4 are more popular among hawaiian women who traditionally wear a single flower. This plant is also used in the preparation of commercial teas. Hence, this plant, while advancing its own individual functions such as reproduction and survival, also advances a larger function for the ecosystem as well as for humans (vitullo, 2009; ames, 2013).

Bioactivity of Hibiscus Components

Hibiscus is one of the medicinal plants that generally find applications in treating diseases such as oxidative stress like hypertension and cancer. This is because they are made up of strong antioxidants like alkaloids and flavonoids / anthocyanins. Anthocyanins are useful in therapy against cardiovascular diseases and cancer (trevisanto, 2000) and age related conditions such as dementia or alzheimer's disease (commenges, 2000; milugo, 2013). Flavonoids have the ability to induce human protective enzyme systems. They have also been found to have protective effects against many infectious bacterial and viral diseases including degenerative diseases such as cardiovascular diseases, cancers, and other age-related disorders (cook, 1996; kumar, 2013; filippo, 2014). Flavonoids also have antibacterial, antiviral (critchfield, 1996; cushnie, 2005), anticancer and anti-inflammatory properties. Flowers of the plant contain ascorbic acid whose biological role is to act as a reducing agent by donating electrons in several enzymatic reactions and a few non-

enzymatic ones. The one-and two-electron oxidized forms of vitamin c that is, semi hydro ascorbic acid and dehydro ascorbic acid, respectively, can be reduced in the body by glutathione and nadh- dependent enzymatic mechanisms (meister, 1994; ewadh 2014). The leaves and stem contain cyclopropane compounds that are inactive at the gaba and glycine receptors. They instead act as an nmda- receptor antagonist (hemmings, 2006; hudson, 2011). It inhibits the ampa receptor and nicotinic acetylcholine receptors, and activates certain k channels (hudson, 2011; borghese, 2012)

Traditional Uses

Hibiscus rosasinensis has been used in siddha medicine, a traditional tamil system from south india, for many centuries. Hibiscus extracts have been used for ages in ayurveda to cure many ailments. The plants have the natural health benefit that can be used to cure diseases naturally. They are used to cure ailments such as cough cold, hair loss and hair greying also. The flowers and leaves of this plant play a major role in hair treatment. These are ground into a fine paste with water and this is generally used as a shampoo plus conditioner. The plant also helps to improve the overall texture and health of hair. Hibiscus is a sweet sour herb and is used in the preparation of herbal teas. It acts as an antioxidant and also helps in the reduction of cholesterol levels (esa, 2010). It has also been used in the traditional medicine for treating colds, loss of appetite, disorders of the respiratory tract. The plant is beneficial as a mild laxative, expectorant and diuretic. The hibiscus rosasinensis has been found to have emmenagogue effects which can stimulate menstruation and in some women, cause an abortion (ernst, 2002; ali, 2005; de boer, 2014).

CardioprotectiveActivity

The medicinal values of the flowers of hibiscus rosasinensishas been mentioned inliterature as useful in disorders of the heart(6).in recent times, both experimental and clinical studies have shown that the dried flower powder of hrs has significant protective effects in ischemic heart disease [ihd] [7,8]. Oral administration of flowers of hibiscus rosasinensisprevents the oxidative stress and the structural changes associated with iri. The mechanism of such protection of chronic oral administration of hibiscus rosasinensismay be due to myocardial adaptation, oxidative stress is mediated through augmentation of cellular antioxidants such as glutathione, sod, catalase [9].Flowers of hibiscus rosasinensisare particularly useful agents, as they could enhance myocardial endogenous antioxidants without producing any cytotoxic effects.A study conducted to investigate the cardioprotectiveeffect of hrs flowers(dried pulverized) showed that hrs flowers augmentedendogenous antioxidant compounds of rat heart and also prevented the isoprotenelol induced myocardial injury.

Antioxidant ActivityAnd Cognitive Enhancing

Hibiscus rosasinensisflowers million contain anthocyanins, which may be responsible for its antioxidant effects.(10)alzheimer's disease (ad) is a neurodegenerative disease causing memory loss and dementia, which mostly affects the elderly population.(11)the pathophysiology of ad is complex including defective beta-amyloid (aβ) protein metabolism, abnormalities of glutaminergic, adrenergic, serotonergic and dopaminergic neurotransmission, and the potential involvement of inflammatory and oxidative pathways.[12] the drugs with antioxidant effects might be beneficial for preserving brain function. Antioxidant enzymes are involved in the reduction of oxidative stress.[13] antioxidant enzymes display the reduced activities in the affected brain region of alzheimer's disease patients. Antioxidant enzymes display
The reduced activities in the affected brain region of patients of alzheimer's disease. Moreover, the reduction in the level of intracellular oxidized protein under these conditions has been associated with the improvement of cognitive and/or psychomotor functions (14). Hibiscus rosasinensis may be useful in the treatment or prevention of various cognitive disorders.

Anti – Bacterial Activity

Most of the flower extracts have an antibacterial activity against the human pathogens such as e. Coli, b. Subtillis, p. Aeruginosa, s. Aureus, streptococcus sp. Salmonella sp. The crude extracts containing multiple organic components including flavonoids, tannins, alkaloids, triterpenoids, all of which are known to have antibacterial affects. Flower extract contain phenolics compounds like tannins that are very good antimicrobial agent[15]. Flavonoids especially are known to be effective antimicrobial agent against a wide arrayof microorganisms. The activity is attributed to their ability to complex with extra cellular and soluble proteins and with bacterial cell wall[16].Most of the extracts showantibacterial activity against e. Coliwhich are common member of the normal flora of large intestine. It is predominant facultative organism in the gastrointestinal tract and colonizes the tract within hours or few days and is responsible for causing diarrhea.Pseudomonas sp. Causes urinary tract infection, respiratory system infection, dermatitis soft tissue infection, gastrointestinal infection and a variety of systemic infection. Thus the extractsof hibiscus rosasinensiscan be used as an important antibiotic to cure above mentioned disorders caused by the different strains of bacteria.

Wound Healing Activity

Wound healing is the process of repair that follows injury to the skin and other soft tissues. Following injury, an inflammatory response takes place and the cells below the dermis begin to increase collagen production. Later, the epithelial tissue (the outer skin layer) is regenerated.(17) topical application of h. Rosa sinensis improved wound contraction and closure and the effects were distinctly visible starting from 4th post-wounding day. Flavonoids promote the wound-healing process mainly due to their astringent and

antimicrobial properties which appear to be responsible for the wound healing.[18] the wound-healing property of h. Rosa sinensis flower extract may be attributed to its high flavonoid content.

Collagen is a major protein of the extracellular matrix and is the component that ultimately contributes to wound strength.[19] the healing process depends, to a large extent, on the regulated biosynthesis and deposition of new collagens and their subsequent maturation.[20] assessment of collagen content in granulation tissues of control and experimental wounds clearly suggests that h. Rosa sinensis enhances collagen synthesis and deposition. Wound contraction, increased tensile strength activity support further evaluation of *h. Rosa sinensis* in the topical treatment and management of wounds.

Anti-Inflammatory Activity

Inflammation is a normal protective response to tissue injury caused by physical trauma, noxious chemical or microbial agents. It is the body's response to inactivate or destroy the invading organisms, to remove irritant and set the stage for tissue repair. It is triggered by the release of chemical mediators from specimen injured tissue and migrating cells[21]. Ethanol extracts of flower(22] and leaf(23] of hibiscus rosasinensis l. (red) has been reported to exhibit anti-inflammatory activity.

Abstract

Huntington's disease (HD) is a neurodegenerative genetic disorder that affects muscle coordination and leads to cognitive decline and behavioral symptoms. HD is the most common genetic cause of abnormal involuntary writhing movements called chorea,i.e the name of the disease is called Huntington's chorea. Tetrabenazine (Xenazine) is specifically approved by the Food and Drug Administration to suppress the involuntary jerking and writhing movements associated with Huntington’s disease.Currently available drugs like Citalopram, Fluoxetine, Sertraline, Tetrabenazine, Amantadine, levetiracetam (Keppra)are only symptomatic.In this review we are discussing about Amantadine ,Levetiracetam ,clonazepam and Tetrabenazine for the treatment of Huntington’sdisease.It is one of the common disease in old age people,so to study the drugs like Amantadine,Levetiracetam,Clonazepam,Tetrabenazine are effective in the treatment of Huntington's disease

Key Words: Huntington’s disease, neurodegenerative diseases, chorea, Parkinsonism

Introduction

Globally, millions of people each year are getting affected by various neurodegenerative diseases and the incidences are increasing further significantly with the extended life expectancy. World Health Organization (2006) reported that the number of older people of more than 65 years age is expected to increase to approximately 1 billion in 2030 worldwide [1]. Therefore, the percentage of aged population in developing countries would increase from 59% to 71% worldwide[2]. Thus, aging is implicated in onset and progression of several neurodegenerative diseases including Huntington's disease(HD),Alzheimer's disease(AD),Parkinson's disease(PD) are characterized by selective loss of anatomically or physiologically related neuronal systems[3].Neuropathologically,these are characterized by abnormalities of relatively specific regions of the brain and specific population of neurons [4].Among the above said neurodegerativediseases, HD is movement disorder is characterized by choreatic movements, dystonic symptoms and rigidity. Hence, this review focuses the Huntington's disease and its treatment.

Huntington's Disease

Huntington's disease (HD) is an autosomal dominant, neurodegenerative disorder characterized by by a triad of chorea, cognitive symptoms and behavioral changes, as well as various hyper-and a hypokinetic movement disorder, of which chorea is more prominent[5]. In patients with HD, chorea has a deleterious effect on coordinated limb movements [6,7]. Although there is no established treatment to delay the onset or forestall the progression of HD, symptomatic treatment of chorea may be beneficial in some individuals as it may have a

favourable impact on motor function, quality of life and safety[8].

Molecular Pathogenesis of HD

Gene mutation play pivotal role in the mechanism of the pathogenesis of HD. The dynamic gene mutation of CAG (cytosine-adenine-guanine) repeat in the Huntington (HTT) gene, which is transcribed into an abnormal protein with an elongated polyglutamine tract. Polyglutamine HTT accumulates and is changed in its function in multifaceted ways related to the numerous roles of the normal protein. This Polyglutamine HTT protein is reported to expressed in variousregions of the brain and in other organs[8]. The striatum of the brain is the major region involved in the disease process, it is also reported that other systems are involved as well. Thus, the overwhelming knowledge in the pathogenesis of HD led to the development of new therapeutic strategies based on specific molecular pathways for symptomatic and disease course-modifying treatment. It has been said that the most proximal way to handle the disturbed protein is to hinder the gene transcription, translation and proteins synthesis. Other mechanisms include modulation of energy and intracellular signaling, induction of factors potentially leading to neuroprotection, as well as modulation of glial function. Several clinical trial studies have shown based on these approaches andtherapy will be a based on the combination of these approaches harmonized with symptomatic treatments[8].

The transcription of DNA into mRNA is highly regulated process in the cell. The expression of protein coding genes is regulated in an orchestrated and elaborate manner, involving several transcription factors which interact with each other and with the regulatory DNA elements that specify the activity of the gene. Currently, it came to light that HTT has an important role in transcription; a range of methods have shown that both wild-type and mutant HTT interact with numerous transcription factors. Further, microarray studies haveconfirmed that various transcriptional pathways are impaired in HD.Other important transcription factors seem to interact with HTT in the nucleus. Among them, the Gln-Ala repeat transcriptional coactivator CA150 has been found to associate with both normal and mutant HTT[9]. Moreover, it has been demonstrated that CA150 protein levels increase concurrentlyas disease increases, which implies that CA150 accumulates in response to HTT aggregation and that this interferes with gene transcription in HD brain samples. Furthermore, an expansion in the polyQ region of TATA box-binding protein (TBP) is known

to induce spinocerebellar ataxia type 17 (SCA-17)diseases, which shows overlapping features with HD[10]. Interestingly, HTT might also function as a transcriptional repressor,it has been shown to interact directly with repressor complexes containing nuclear corepressor protein and Sin3A in a polyQ-dependent manner as demonstrated by yeast two-hybrid analysis[11]. Nuclear corepressor protein and Sin3A act with other transcriptional DNAbinding proteins to repress the transcriptional activation of nuclear receptors such as the thyroid and retinoic acid receptors. Accordingly, mutant HTT might interfere not only with nuclear co repressor protein and Sin3A function, but also with signaling pathways involving nuclear receptors.

Chaperones and the Proteasome

One feature of HD, along with other neurodegenerative diseases, is that inclusions have been found to be ubiquitinated and associated with several proteasome subunits, which strongly suggests a failure in the degradative machinery of the cell. If chaperones cannot refold abnormal proteins correctly, they then promote their subsequent ubiquitination, which ultimately directs them to the proteasome for degradation[12].Several lines of evidence have indicated that impairment of the ubiquitin-proteasome system (UPS) is central to the pathogenesis of polyQ disease*i.e.,* in HD. The eukaryotic proteasome is incapable of digesting peptides containing stretches of 9–29Q residues, and these peptides must be released for further hydrolysis by unidentifiedpeptidases[13]. Therefore, the attempted digestion of pathogenic polyQ tracts might result in aggregation-prone polyQ-containing fragments being released from the proteasome, or the failure of these tracts to exit might impair proteasome function. Consistent with this, transient transfection of HTT fragments containing a pathogenic polyQ repeat caused almost complete inhibition of the UPS in a cell-based UPS reporter system, which implies that protein aggregation directly impairs the function of the UPS [14].

Etiology

Huntington's disease is an autosomal dominantly inherited disease caused by an elongated CAG repeat on the short arm of chromosome in the Huntingtongene. This gene codes for the Huntingtonprotein on exon 1, it contains the CAG tract. The wild-type contains a CAG repeat, coding for a polyglutamine stretch in the protein at that site in the range from 6 to 26. Huntington's disease is associated with 36 repeats or more. Definite clinical manifestation

will occur if the number of repeats exceeds more than 40. The range 36-39 leads to an incomplete penetrance of the disease or to a very late onset. The range between 29 and 35, they called as intermediate alleles and it is unstable, which means that these alleles are prone to changes during reproduction. Copying the gene may lead to mistakes and very often leads to elongation and seldom to shortening. This phenomenon is mainly seen in the male line of reproduction[15].

An inverse correlation has been described between the length of the repeat and the age at onset, determined by the first motor manifestation. The longer the CAG repeat, the earlier the onset. When the disease starts before the age of 20 years, so-called juvenile Huntington's disease (JHD), the repeat often exceeds 55[16]. The length of the repeat determines about 70% of the variance in age at onset and gives no indication at all about the initial symptom, the course, or the duration of illness. The only correlation now described is the faster weight loss associated with a longer CAG repeat[17]. Anticipation phenomenon is seen in Huntington families in the paternal line of inheritance.

The normal wild-type Huntington protein plays a role in synaptic function, is necessary in the post-embryonic period, possibly has an anti-apoptotic function and is possibly protective against the toxic mutant, Huntington[4]. There is evidence that the mutant form leads to a gain of function as well as to a loss of function.

Clinical Description

The nuclear symptoms and signs of Huntington’s disease (HD) consist of motor, cognitive and psychiatric disturbances. Other less well-known, but prevalent and often debilitating features of HD include unintended weight loss, sleep and circadian rhythm disturbances and autonomic nervous system dysfunction[5]. The mean age at onset is between 30 and 50 years, with a range of 2 to 85 years. The mean duration of the disease is 17-20 years. The progression of the disease leads to more dependency in daily life and finally death. The most common cause of death is pneumonia, followed by suicide.

Signs and Symptoms

The characteristic motor changes are involuntary, unwanted movements. Initially, the movements often occur in the distal extremities such as fingers and toes, but also in small

facial muscles. For bystanders these muscle twitches are often invisible or can be explained as nervousness. In daily life, walking becomes unstable and the person can look as slightly drunk. Gradually the unwanted movements spread to all other muscles from distal to more proximal and axial. Choreatic movements are present all the time the patient be awake. No single pattern exists, but facial choreatic movements can lead to a continuous movement of facial muscles where for instance an eyebrow is lifted, an eye closed, the head is bent or turned while the tongue is protruded with the lips pouting. The most prominent are the extension movements of the long back muscles. Talking and swallowing gradually become more problematic leading to choking at any time in some patients. In later stages the patient even becomes mute. Dysarthria and dysphagia become very prominent during the course of the disease. All patients develop hypokinesia, akinesia, and rigidity leading to a slower pace of all activities (bradykinesia: slowness of movement) and a severe hesitation in embarking on a movement (akinesia: difficulty in starting movements)[11]. The balance between chorea and hypokinesia is determined individually. The extremes are on the one hand the younger patient with an overwhelming rigidity (Westphal variant) and on the other hand the very old patient severely affected in the last stage of the disease with a long duration of illness, bed-bound with rigidity and flexion contracture in the extremities. Dystonia is characterised by slower movements with an increased muscle tone leading to abnormal posture, for instance torticollis, but also rotation of the trunk or limbs. Dystonia (for instance torticollis) can be the first motor sign in Huntington's disease. Other unwanted movements include tics, comparable to the ones seen in Tourette syndrome, but these are fairly rare. Cerebellar signs can appear sporadically, similar to the presence of hypo- and hypermetria[7]. Walking is often described as 'drunk' or 'cerebellar ataxia'-like. Distinguishing between choreatic and ataxic walking is very difficult. Pyramidal signs (Babinski sign) are present incidentally.

Cognitive decline is the other main sign of HD and can be present long before the first motor symptoms appear, but can also be very mild in far advanced stages of the disease. The cognitive changes are particularly in relation to executive functions. In normal conditions, cognitive and motor behaviour is goal-directed and planned. Normally individuals are able to distinguish what is relevant and what can be ignored, but patients with HD lose this capability. The patients are no longer able to organise their life or to plan things which in the past were simple [8]. They lose flexibility of mind, and can no longer make mental adjustments. Misjudgements lead to complicated situations, with patients no longer reacting

as they did in the past or in a way that the environment expects. Language is relatively spared. Memory certainly becomes impaired, although the semantic memory can be spared to a certain extent [9]. All psychomotor processes become severely retarded.

If the first symptoms and signs start before the age of 20 years, the disease is called Juvenile Huntington's disease (JHD). Behaviour disturbances and learning difficulties at school are often the first signs. Motor behaviour is often hypokinetic and bradykinetic with dystonic components. Chorea is seldom seen in the first decade and only appears in the second decade. Epileptic fits are frequently seen. The CAG repeat length is over 55 in most cases. In 75% of the juveniles the father is the affected parent[8].

Secondary Signs and Symptoms

From early on, an unintended weight loss has been reported in all patients. As more attention is now paid to this phenomenon, the loss seems to be a little less severe, the cause being diverse. Although it seems logical to think that chorea should play the main role in weight loss, it has been shown that there is no relation between weight loss and chorea or other movement disorders[10]. More practical issues, such as slower functioning, decreased appetite, difficulty handling food and swallowing certainly play a role. But hypothalamic neuronal loss is also a causative factor.

Attention has only recently been focused on sleep- and circadian rhythm disturbances of patients with HD .Autonomic disturbances can result in attacks of profuse sweating.

Psychiatric symptoms are very frequently present in the early stage of the disease, often prior to the onset of motor symptoms. The percentage of patients with psychiatric signs varies between 33% and 76% depending on the methodology of the study[4]. Because of their impact on daily life, these symptoms and signs usually have a highly negative impact on functioning and on the family [5]. The most frequently occurring sign is depression. The diagnosis is difficult because weight loss, apathy and also occur in HD. Usually there is low self-esteem, feelings of guilt and anxiety. Apathy is related to disease stage, whereas anxiety and depression are not. Suicide occurs more commonly in early symptomatic individuals and also in pre manifest gene carriers. Around the time of the gene test and the stage when

independence diminishes are the most risky periods for suicide. Anxiety also occurs frequently (34-61%), sometimes in relation to uncertainty about the start and or the course of the disease. Obsessions and compulsions can disturb the patient's life and also lead to irritability and aggression. Irritability is often the very first sign, in retrospect, but in fact occurs during all stages of the disease [7]. The way irritability is expressed varies from serious disputes to physical aggression. A loss of interest and increasing passive behaviour are seen as part of the apathy syndrome. It can be difficult to discriminate apathy from depression. Psychosis may appear, mainly in the later stages of the disease. In most cases this goes together with cognitive decline. The complete clinical picture is comparable to schizophrenia with paranoid and acoustic hallucinations. In the early stages, hyper-sexuality can cause considerable problems in a relationship. In the later stages hypo-sexuality is the rule.

Diagnosis

The clinical assessment of the symptoms and signs of HD is important for patient, family and care-givers. To follow the patient systematically, mainly for research purposes, several scales have been developed. The best known are the Shoulson and Fahn capability scale and the Unified Huntington Disease Rating Scale (UHDRS). The UHDRS consists of a motor, behaviour, cognitive and functional part, preceded by a history and medication scheme. For the behaviour signs a new scale was developed by Craufurd, the Problem Behaviour Scale (PBS).The diagnosis is based on the clinical symptoms and signs in a person with a parent with proven HD. First, it is obligatory to take a precise history from the person with symptoms followed by a detailed family history[5,6,7]. When all information has been obtained the diagnosis is not very difficult, although non-specific clinical pictures can be misleading. Also when the parent is not known or has died due to another cause at a young age, the clinical picture can be difficult to recognise. It is often necessary to request old information in the form of medical records and autopsy reports. The current gold standard is DNA determination, showing a CAG-repeat of at least 36 on the *Huntington gene* on chromosome 4. Before 1993, a family history with clinical and morphological verification in at least one of the parents or grandparents was obligatory[14].The clinical criteria currently necessary are still motor changes with or without psychiatric or cognitive changes. However,

in most cases a combination of the three main signs is present. The combination with the family history is sufficient for diagnosis. No imaging, general blood tests or other diagnostic tools are helpful. Several studies are now focussing on changes in function and changes in brain imaging (MRI) before clinical overt manifestation is present.

Treatment of Huntington's Disease

Many agents and surgical procedures have been evaluated in HD for their anti-choreic efficacy including dopamine depleting agents, dopamine antagonists, benzodiazepines, glutamate antagonists, acetylcholinesterase inhibitors, dopamine agonists, anti-seizure medications, cannabinoids, lithium, deep brain stimulation, and fatal cell transplantation.Therapeutic drug for the HD is usually minimize its chorea and other movement disorders.The monoamine depletortetrabenazine (TBZ) has been shown to effectively reduce hypokinetic movement disorders especially chorea in HD[18]. TBZ carriesa less severe risk of developing tardive dyskinesia[19]. TBZ is well tolerated and serves as a good drug candidate to start medical treatment of choreatic movements even in early stages[20].Possible side effects of TBZ include depression, Parkinsonism, insomnia, akathisia, and sedation. Coming to the drug regimen, the dosage initially starts with 12.5 mg/day an6+d it can be increased as 12.5 mg three times per day. There is no marked maximum dose for this is reported in literature however it is usually limited to 100 mg/day. Its pharmacokinetics effectincludes strong cytochrome P450 2D6 inhibitors for instance, selective serotonin reuptake inhibitors such as paroxetine, fluoxetine, or other antidepressants such asbupropion or the individual turns out to be a CYP2D6 slow metabolizer by genotyping, the maximum dose should be restricted to half, although no distinguishing features have been found in patients exhibiting various CYP2D6 activities[21].Undoubtedly, in spite of itsbeneficial effects on chorea certain cognitive functions can worsen under medication with TBZ[22].

Neuroleptic drugs are also preferentially used for the HD If both chorea and psychiatric symptoms like agitation and psychosis are predominant features, these drugs are act by blocking the dopamine transmission[22].Neuroleptic drugs such as haloperidole, fluphenazineor chlorpromazine are commonly used in the HD patients if chorea is very severe or psychosis is accompanied by aggressiveness.Neuroleotics treatment is contraindicated in HD patients show Parkinsonian-like symptoms because medication with

neuroleptics can worsenParkinsonism. Several atypical neuroleptics have been chosen to treat chorea in HD patients. Clinically, Olanzapine, risperidoneand aripiprazole have been reported to improve chorea in HD patients.Sedation and obesityis a common side effectassociated with neuroleptics. Weight gain can even be of advantage for HD patients since unintended weight loss is in many cases a progressing burden in HD[23].

Benzodiazepines Chorea is known to worsen in psychologically demanding situations or under stress. Hence, low dosages of antidepressant *i.e.*,benzodiazepines can be added to the medication transitionally to cushion these emotional effects. The risk of drug abuse and dependency is the most drawbacks[22].

Amantadine, an antiviral and an antiparkinsonian drug also employedfor treatment of chorea is discussed controversially, since results of the present trials are not concordant[24,25]. Accordingly, this N-methyl-D-aspartate excitatory receptor antagonist could be an option in individual patients to improve chorea.

Riluzole is used for thetreatment of chorea in HD have diminished. Notable side effects were reported, but restricted to dose of 200 mg/day. However, Riluzole does not serve as first-line medication in the treatment of chorea in early symptomatic HD patients but it is recommended in third position for treating in HD[22].

During the course of the disease, the patient requires more care, which can also help his/her partner, for example by having a nurse at home to help with showering. The burden for the caregiver can become too heavy and so help must be found in day-care institutions, usually connected to nursing home facilities. In the period that follows the patient moves into a transition phase and eventually a 24-hour care situation. Throughout the whole process of increasing dependency, psychological help is often needed for the caregiver, who has to deal with increasing responsibilities while losing contact with his or her former partner. Partner groups can be very useful. In general, lay organisations play an enormous role in educating caregivers, patients and families.Medical and non-medical treatment must be individually tailored, as the symptoms and signs differ by person and over time tremendously. Ideally

treatment of patients and their families should be organised by a multidisciplinary team. Treatment is intended to improve quality of life. To date, no cure is available unfortunately.

Conclusion

In light of this review, it has been confirmed that the therapeutic treatment of HD include only to improve the symptoms and afford neuroprotection. Therapeutic options are still limited to symptomatic medication and supportive approaches. Current drug therapy has no effect on the progression of disability, and the need for any pharmacological treatment should be carefully considered. Hyperkinesias and psychiatric symptoms may respond well to pharmacotherapy, but neuropsychological deficits and dementia remain untreatable. Pharmacological intervention in the treatment of the movement disorder of HD is aimed at restoring the balance of neurotransmitters in the basal ganglia.A low level of evidence exists to support the use of physiotherapy for addressing impairments of balance, muscle strength, and flexibility. There was a small amount of evidence to support the use of speech pathology for the management of eating and swallowing disorders. The current evidence is insufficient to make strong recommendations regarding the usefulness of physiotherapy, occupational therapy, or speech pathology for people with Huntington's disease.

As discussed in this review, the molecular physiopathology of HD is very complex. Hence,the future therapy should combine number of drugs targeting different molecular targets in order to improve the chorea like symptoms and thereby afford neuroprotection. Since the single cause of HD is precisely known, and this disorder may be considered a paradigm for disease modifying treatment of other neurodegenerative disorders. Further studies are warranted in the arena of clinical, genetic and neuropathological factors that causes HD.

Abstract

Disorders related to perceiving loud sounds can represent a serious challenge to patients in a dental setting. In this paper a review of what is known of hyperacusis—the prevalence, causes, symptoms and approaches to treatment. Beginning with definitions, because even basic terminology still varies in this under-researched area. Hyperacusis (also spelled hyperacousis) is a health condition characterized by over-sensitivity to certain frequency and volume ranges of sound (a collapsed tolerance to usual environmental sound). Difficulties in tolerance towards listening to everyday sounds is observed in severe hyperacusis, some of which may seem unpleasantly or painfully loud to that person but not to others [1][2].There is no objective test for hyperacusis. Most people who develop hyperacusis will be referred to an ear doctor and receive a thorough evaluation including a full audiological assessment to determine the state of the auditory-vestibular system. For patients, hypersensitivity of hearing may evoke anxiety and even fear. This can be true for specific sounds or for sound in general. The links between the central auditory system and areas of the brain implicated in anxiety and fear are now under close scrutiny.Hyperacusis can come on suddenly or gradually. It can in the early stages affect the ear on one side but generally speaking, within a short time, the condition is almost always bilateral. It can be mild or severe. Often, people who have hyperacusis also have tinnitus or phantom noises in their auditory system (ringing, buzzing, chirping, humming, or beating). Research has shown that about half of all people who have tinnitus, also have reduced tolerance for moderate or loud sounds, known as hyperacusis.

Key Words :*hyperacusis, over-sensitivity, auditory, tinnitus*

Introduction

Hyperacusis is described as an‘unusual tolerance to ordinary environmental sounds’ [3] and, more pejoratively, as ‘consistently exaggerated or inappropriate responses to sounds that are neither threatening nor uncomfortably loud to a typical person’ [4]. Common to both is the implication that the experience can be evoked by sounds of low intensity and that sounds in general, rather than specific sounds, are problematic. This is less true of phonophobia (fear of sound) and the recently proposed misophonia (dislike of sound) [5], both of which carry a suggestion that the intolerance may be specific to certain sounds with emotional associations. In terms of neurology, phonophobia tends to be utilized for the loudness intolerance reported by some patients with migraine. For the wider types of hearing hypersensitivity, therefore, the term hyperacusis is preferable. Loudness recruitment[6][7] describes an experience commonly associated with cochlear hearing loss and specifically with dysfunction of the outer hair cells of the organ of Corti: with a rising sound level, the perceived loudness becomes increased faster than normal [8].This phenomenon may be distinguished from hyperacusis if the individual perceives sound of moderate intensity as uncommonly loud (recruitment) or sound of reduced intensity as loud in an uncomfortable manner (hyperacusis) but both the experiences are not mutually exclusive.

Decreased amount of significant epidemiological data is a major shortcoming of the published work on hyperacusis. Fabijanska et al. [9] undertook a postal questionnaire of tinnitus in Poland which included an unspecified question on hyperacusis. Of the 10349 respondents, 15.2% reported hyperacusis (12.5% of males, 17.6% of females). Regional differences were also reported. A weakness of this report is the lack of specificity. More recently Andersson and co-workers [10]investigated the prevalence of hyperacusis in the adult Swedish population. Two methods were used—an internet study, wherein visitors to the website of a Swedish broadsheet newspaper were invited to complete a web-based questionnaire; and a postal population study [11]. Ofa total of 1167 individuals, 595 responded upon the web banner, response rate of 52%. The point prevalence of hyperacusis in this group was 9%. The postal group comprised 987 individuals of whom 589 responded (response rate 60%) and the point prevalence was 8% [12]. Participants were not asked if they had ever sought a medical opinion regarding their hyperacusis. Incidence data for hyperacusis do not seem to have been reported anywhere [13].

A coincidence of tinnitus complaint and of experiences of hyperacusis has been widely note. In patients going to tinnitus clinics with a primary complaint of tinnitus, the prevalence of hyperacusis is about 40%; 9–11 and in patients with a primary complaint of hyperacusis the prevalence of tinnitus has been reported as 86% [14]. The apparent link has led to speculation about common mechanisms [15]. Until recently it has not been possible to quantify the handicap associated with hyperacusis, but two instruments have now been published for this purpose. Khalfa et al. [16] describe data from a self-report hyperacusis questionnaire with 14 items 'normalized' on 201 individuals who had answered a recruitment advertisement. Principal component analysis indicated that three factors accounted for 48% of the variance—attentional, social and emotional. With a 27-item questionnaire examined in 226 patients with hyperacusis Nelting et al. [17] reached similar conclusions: 51% of the variance was accounted for by cognitive reactions, actional/somatic behaviour and emotional factors.

Causes

In the great majority of cases, no underlying medical condition can be found. The conditions in which hyperacusis has been reported as a symptom have been reviewed by Katzenell and Segal[18].Since the facial nerve innervates the stapedial reflex, which is a mechanism for reducing the perceived intensity of impulse sound, these conditions may reduce the efficacy of that reflex and hence increase the perceived intensity of sound.

Williams syndrome is a disorder characterized by deficits in conceptual reasoning, problem solving, motor control, arithmetic ability and spatial cognition, with an incidence of 1 in 20 000 live births. As many as 90% of individuals with this syndrome report hyperacusis [19]. The common causes of hyperacusis are found to be hearing loss, noise injury, head injury or whiplash type injury,acoustic trauma, i.e. airbag explosion or gunshot, adverse reaction to medication or surgeries, particularly central nervous system drugs, chronic ear infections,auto immune disorders. The most common causes of hyperacusis have been found to be noise injuries and head injuries by far. Neck injuries can also contribute, i.e., whiplash. There remain huge areas of medical scientific research and data accumulation that must be explored before we can really begin to define and understand the different types of hyperacusis, and the origins of this troubling disorder.The frequently encountered cause of hyperacusis is overexposure to excessively high decibel levels (or sound pressure levels) [20].

Mechanisms

Sahley and Nodar considered the observation that hyperacusis (and tinnitus) appear to increase in extent at times of tiredness, anxiety or stress. They hypothesize that, during stress, endogenous dynorphins are released into the synaptic region beneath inner hair cells. This might potentiate the neurotransmitter glutamate, causing sound to be perceived with excessive loudness. The model applies both to externally generated and to internally generated (tinnitus) sound, but empirical evidence in support has not yet been forthcoming [21].

The high prevalence of hyperacusis in Williams syndrome led Marriage and Barnes to consider the mechanism in that condition and the extent to which it might be generalized to other individuals. Their suggestion that 5-HT might be implicated was based partly on the clinical observation that hyperacusis tends to occur in other conditions where 5-HT unction is thought to be disturbed—namely, migraine, depression and post-traumatic stress disorder. 5-HT does appear to have a role in modulating auditory gain and the determination of significance of sound. However, there is no evidence that 5-HT disturbance contributes to hyperacusis of non-syndromic types. Moreover, even in Williams syndrome the excessive auditory gain may be explained partly by the high incidence of otitis media with effusion and the associated conductive hearing loss [22].

Symptoms

In cochlear hyperacusis (the most common form of hyperacusis), the symptoms are ear pain, annoyance, and general intolerance to any sounds that most people don't notice or consider unpleasant. Cochlear hyperacusis may cause crying spells or panic attacks. As many as 86% of hyperacusis sufferers also have tinnitus [2][23] .In vestibular hyperacusis, the sufferer may experience feelings of dizziness, nausea, or a loss of balance when sounds of certain pitches are present. The extent to which a hyperacusis patient is affected relies not only on the overall severity of that person's symptoms but also on whether the person can detect sounds in that frequency range at the volume in question, as well as on the person's preexisting tone and severity of startle response. Anxiety, stress, and/or phonophobia can be found in both types of hyperacusis. Individuals suffering from either form of hyperacusis may develop avoidant behavior in order to try to avoid a stressful sound situation or to avoid embarrassing themselves

in a social situation that might involve noise. Regular everyday sounds such as closing doors, ringing phones, running water, ticking clocks, chewing gum, cooking, normal conversation, eating, dishes, and other sounds will hurt his/her ears.

Hyperacusis in children

Reduced tolerance to sounds seems particularly common in children who have had a temporary hearing loss due to wax or otitis media with effusion that has then been corrected. It is also noted in children with learning and/or social and communication difficulties including those on the autistic spectrum or with Williams Syndrome. Common troublesome sounds include sounds of vacuum cleaners, washing machines or emergency vehicles. The child's reaction ranges from covering ears to crying and screaming. For children with mild distress, management may involve an explanation of the symptom and advice on coping strategies. For those children who are markedly distressed, the management may involve auditory desensitization, behavioral desensitization or both. A multi-agency or multi-disciplinary approach is recommended [24].

Assessment

Tyler et al. (University of Iowa, USA) suggested the following classification of hyperacusis:

- "Loudness hyperacusis" - some moderately loud sounds are very loud;
- "Annoyance hyperacusis" - some sounds are annoying (not always loud);
- "Fear hyperacusis" - patients are afraid of some sounds (not always loud).

Questionnaires to assess the severity and disability associated with each of the above categorieswere used in a study of over 200 people with hyperacusis. This showed that louder sounds are generally more annoying and softer sounds are less likely to evoke fear hyperacusis. The most common etiological factor is noise exposure. In 10% the symptom is unilateral. About 90% report concurrent tinnitus. Music, screaming and sirens are the most common sounds associated with fear hyperacusis. Loudness and annoyance hyperacusis are more closely linked to one another than they are to fear hyperacusis. Some patients with severe hyperacusis are also bothered by strong smells, tastes and bright lights and report headaches and balance problems. It

was suggested that use of this classification facilitates the treatment of hyperacusis patients using a protocol called tinnitus activities treatment [25].

Jastreboff and Jastreboff (Emory University, USA) proposed a different taxonomy for decreased sound tolerance (DST); defining DST as the presence of negative reactions experienced by a subject as a result of exposure to sounds that would not evoke such aversive reactions in the average listener. They suggested that DST can be subdivided into hyperacusis, misophonia, or a combination of these conditions.In this classification, hyperacusis is defined as a negative reaction to a sound dependent only on its physical characteristics, namely its spectrum and intensity. The sound's meaning and the context in which it occurs are irrelevant. Misophonia is characterized as negative reactions to a sound with a specific pattern and meaning to an individual patient. In misophonia the physical characteristics of the sound are secondary and the reactions to the sound are thought to depend on non-auditory factors such as the patient's previous evaluation of that sound and the context in which the sound is presented. Misophonia can include a variety of negative emotions such as dislike, annoyance, hate, discomfort, fear. In this classification a further type of DST, phonophobia, is defined as a subset of misophonia in which fear is the dominant factor. A hypothesis for the mechanisms of hyperacusis and misophonia was proposed together with a treatment paradigm based on tinnitus retraining therapy (TRT) [26].

How Hyperacusis Affects People

People with hyperacusis can have very different levels of distress, and our clinical experience is that they often are more handicapped than those with tinnitus. Hyperacusis can influence emotional well-being, hearing, sleep, and concentration. This is the basis for Tinnitus Activities Treatment [27]which is also applied to hyperacusis patients.Jüris, Andersson, Larsen, and Elselius (2013) studied a group of 62 patients with hyperacusis and reported that about 47% fitted the diagnosis of having an anxiety disorder. Some patients complain that their hyperacusis interferes with speech perception, particularly in noise. How hyperacusis affects the coding of speech and separating speech from noise at these higher levels is unknown. Because many people with hyperacusis also have hearing loss, it is difficult to isolate peripheral and central effects. Furthermore, we should not forget that many with hyperacusis appear to have normal hearing thresholds. Some people with hyperacusis report that they are awakened from sleep by

sounds or that they do not sleep well because of the anticipation of a loud or annoying sound. Some report that they have difficulty concentrating in anticipation of a loud or annoying sound. A particular problem for those with hyperacusis, and one that is not always appreciated, is that they often have to move around in different areas with varying noise levels throughout the day. Some areas might be quiet, some might have moderate noise levels, and some might have high enough levels that noise protection is warranted. This might naturally lead to fear hyperacusis. It would be of interest to apply the World Health Organization categorization of Functional Impairments as has been done for tinnitus (Tyler, 1993; Tyler et al., 2009). For example, the primary functions impaired could be emotions, hearing, sleep, and concentration. This would limit activities of socialization, work, and education and would have an economic impact. Many with severe hyperacusis, notably fear hyperacusis, experience dire emotional problems (notably anxiety and depression). Juris et al. (2013) reported that 56% of patients (35 of 62) with hyperacusis met criteria for a psychiatric disorder. Most had a social phobia and/or a generalized anxiety disorder. A common perspective among clinical otologists and audiologists is that hyperacusis is primarily a psychological disorder. One can imagine at least two scenarios. Auditory system abnormalities could lead to hyperacusis. This could lead to anxiety and depression. Another scenario is that brain abnormalities could lead to mental illness and dysfunction (and, therefore, a psychiatric disorder) and that hyperacusis is one symptom resulting from this. This distinction will likely be important in understanding mechanisms. Counseling and sound therapy management addressing both the hyperacusis and the psychological issues resulting from hyperacusis could (at present) be applied regardless of the underlying mechanisms.

Therapy

For many patients, the first reaction to hyperacusis is to protect themselves with ear plugs, muffs or other devices. There is, however, reason to believe that such strategies to decrease the intensity of sound entering the auditory system may further increase the central gain, exacerbating rather than improving the hyperacusis. In the past, patients had little choice but to resort to hearing protection devices since hyperacusis was not widely regarded as a genuine symptom. For tinnitus, tinnitus retraining therapy (TRT) was introduced in 1993,and with minor modifications this has been advocated also for hyperacusis. After evaluation in audiological and

medical aspects, the protocol11 requires classification of the patient according to the tinnitus and hyperacusis state, and then ‘directive counseling’ about the auditory system, about mechanisms of tinnitus and hyperacusis and about the distress associated with them. Binaural sound therapy, from ear-level wide-band generators, is under- taken even when the symptoms are unilateral. Treatment is based on the notion of desensitization, and the sound intensity is increased from a low level gradually over time. No randomized controlled trials have been done on retraining therapy for hyperacusis; they would be hard to design in view of the twin elements of counseling and sound therapy.

Several observational studies [28]have pointed to improvements in loudness tolerance, but the nature of training to do TRT (attendance at an examined course run by the originators) raises concerns about objectivity. For the psychological distress associated with tinnitus, cognitive–behavioral therapy (CBT) has been identified as the treatment of choice [29], and this seems a reasonable strategy to counter the anxiety and stress associated with hyperacusis, together with information counseling, relaxation therapy and sound therapy. No evidence as to the efficacy of such an approach is yet available, and at present CBT therapists in the UK shows little interest in tinnitus or hyperacusis. There is at present some tension between advocates of retraining therapy and advocates of psychological therapy, but the differences between the two are not great. Patients would probably benefit if the insights from both could be brought to bear[30][31].

Conclusion

Hearing is an ability that can be affected or distracted by various means [32][33]. Most jobs involve some level of noise. In some cases, the patient may need to seek other employment or attempt to secure disability with the help of an understanding doctor. Loud noise exposure generally makes the condition worse and exacerbates the accompanying tinnitus. Patients report they perceive sound - even their own voice - as uncomfortably loud and this not only causes tinnitus to increase but may also cause inner ear discomfort or a popping reflex in the ear. In fact some patients actually try to change the pitch of their own voice to accomodate their ears. This may help their ears but a patient can become hoarse in the process.

Abstract

Aim of the dental treatment is to replace the damaged or lost part of tooth structure with materials that restores functions and aesthetics of that tooth. Over the past few years various materials have been introduced for these purposes, amongst those categories implants are more popular in the past few decades. An implant is defined as a "biomaterial which is inserted either partially or completely, into the body for therapeutic, diagnostic, or prosthetic purposes". The attachment of cells to titanium surfaces is an important phenomenon in the area of clinical implant dentistry. The key factor in implant designs is to create surfaces that promote desirable responses in the cells and tissues. Biological fixation between the dental implant surfaces and jaw bones determine the longevity of dental implants. Implant morphology influence bone metabolism, rougher surface stimulates differentiation, attachment and growth of bone cells, and increases bone mineralization,furthermore, the degree of roughness is important. Textured surface also allows ingrowth of the tissues. Various techniques of surface modifications have been studied and applied to improve biological surface properties, which favours osseointegration. The major methods that are studied in the literature review to create implant roughness are acid etching, grit-blasting, titanium plasma spraying, Calcium phosphate coating, electrochemical anadizing and laser treatment.

***Key Words**: Titanium Plasma Spraying, Sand Blasting, Acid Etching, Laser Treatment, Grit Blasting.*

Introduction

Aim of the dental treatment is to replace the damaged or lost part of tooth structure with materials that restores function and esthetics of that tooth. Over the past few years various materials have been introduced for these purposes, amongst those categories implants are more popular in the past few decades. An implant is defined as a “biomaterial which is inserted either partially or completely, into the body for therapeutic, diagnostic, or prosthetic purposes”.[1,2] The attachment of cells to titanium surfaces is an important phenomenon in the area of clinical implant dentistry. The key factor in implant designs is to create surfaces that promote desirable responses in the cells and tissues. Biological fixation between the dental implant surfaces and jaw bones determine the longivity of dental implants.[3] Implant morphology influences bone metabolism: rougher surfaces stimulates differentiation, growth and attachment of bone cells, and increases mineralization; furthermore, the degree of roughness is important. Textured surface also allows ingrowth of the tissues [4,5]. Various techniques of surface modifications have been studied and applied to improve biological surface properties, which favours osseointegration [6,7]. The major methods that are studied in the literature review to create implant roughness are acid etching, grit-blasting, titanium plasma spraying,Calcium phosphate coating, electrochemical anadizing and laser treatment. Dental implant surface technologies have evolved rapidly in the recent times to enhance the bone formation on their surface. Following the placement of the implant, there is a predictable sequence of bone turnover and replacement at the interface that allows the newly formed bone to adapt to microscopic roughness on the implant surface, and even nanotopography has been shown to preferably influence the formation of bone. Chemical composition of the implant surface can differ markedly from bulk composition due to manufacturing, finishing, thermal treatment, blasting, etching, coatings, and even sterilization procedures. Based on these considerations, a careful control of implant surface composition becomes a relevant procedure to produce high-quality devices. Dental implants have become a standard procedure for single tooth replacement in the esthetic zone, providing many advantages but also challenges in sophisticated patients.

Titanium Plasma Spraying

This method consists in injecting titanium powders into a plasma torch at high temperature. These titanium particles projected onto the surface of the implants condense and fuse together

resulting in titanium plasma sprayed (TPS) coating with an average roughness of around 7 μm. [8]This procedure helps in increasing the surface area of the implants. TPS are recommended in regions with low bone density as it increases the surface roughness profile and consequently the surface area. [9] It is considered that the increase in surface area represents an effective increase in osseointegration area providing spaces greater than 50 μm that facilitates the migration of pathogens when the implant surface is exposed to the oral fluids.[10] Advantages of TPS are Reported to increase the surface area of bone implant interface and act similarly to 3D surface, which may stimulate adhesion osteogenesis, Surface area to increase by 600%, Increases tensile strength of bone implant interface and Improves primary stability. [11] modified surfaces can also present osteoconductivity which allows for cell migration to the implant surface promoting the formation of extracellular matrix and bone apposition.[12] It proposed to modify the implant surface without leaving the residues found after the sandblasting procedures. It helps to avoid the nonuniform treatment of the surface and to control the loss of metallic substance from the body of the implant. Baths of hydrochloric acid (HCl), sulfuric acid (H2 SO4), hydrofluoric acid (HF), and HNO3 are used in different combinations. Roughness before etching, the acid mixture, the bath temperature, and the etching time all affect the acid-etching process. The OsseoSpeedimplant was introduced to the market in 2004. The specific surface texture is a result of two subtractive, sequential manufacturing steps. Titanium oxide blasting produces the microscale surface roughness. The subsequent etching with hydrofluoric acid shapes the nanostructure of the implant. A pleiotropic manufacturing effect is the accumulation of fluoride on the surface. Fluoride containing surfaces have been hypothesized to propagate the host-to-implant reaction in early osseointegration. Cell studies have demonstrated that the OsseoSpeed surface promotes a branched cell morphology of osteoblasts and an osteogenic gene expression profile as well as osteoinduction and osteogenesis in mesenchymal stem cells compared to TiOblast implants (DENTSPLY Implants, Mannheim, Germany), the titanium oxide blasted precursor.

Grit Blasting or Abrasive Blasting

Grit blasting, also known as abrasive blasting, is another technique which is used to create surface topographies on the implant surfaces. Blasting is a diffuse mechanical treatments done to obtain rough implant surfaces.[13] grit-blasting procedure is performed by propulsion of particles of different sizes at high velocity such as of silica (sand), alumina, titanium oxide or CaP. [14] This technique is generally employed for descaling and surface roughening of commercial implants there by increasing the surface area of the implant for better osseointegration. [15] Shot peening is a modified method of grit blasting and is used primarily for introducing compressive stresses in the material's surface. It is most commonly used for producing specific surface topographies on various biomaterials surfaces. Surface topography depends on size of particles used blasting.[16] Alumina particles in the size range of 25-75 µm result in mean surface roughness in the range 0.5-1.5 µm, [17,18] where as roughness in the range of 2-6 µm are reported for surfaces blasted with particles of size between 200-600 µm. Use of fine particle size glass particles of 150-230 ìm results in relatively smooth surface.[19] Advantages of blasting includes a secure 3-D interlocking interface with bone, minimal crestal bone remodeling, Short healing timeProvide space, volume for cell migration and attachment and thus support contact osteogenesis.[20] Abrasive blasting can be used to remove - or clean - excess or unwanted materials from a surface. The advantage of the procedure is that it keeps the surface intact, while everything else is removed. There are two main types of blasting: dry and wet. The type of abrasive used in a particular application is usually specific to the blasting method. Dry blasting is usually done with the following: Sand Metallic grit Shot Aluminum oxide (alumina) Silicon carbide Wet blasters are operated with: Sand Glass beads Other materials that remain suspended in water. The exact equipment used depends, to a large extent, on the specific application and type of abrasive. Industries that use abrasive blasting include: Shipbuilding, Automotive, Metal finishing, Foundry, Surface coating. Other industries that involve surface preparation and painting. Common applications are engravings for monuments and buildings and cleaning boat hulls, etc.

Acid Etching

Metallic implant is immersed into an acidic solution, which erodes its surface, creating pits of specific diameter and shape. [21]Most commonly used acid-etching agents are hydrofluoric, nitric, sulfuric acids and combinations. Etching of the implant surface produces irregular

micropores with approximately 3-5 μm in diameter and 2-3 μm in depth. [14] Such a etched surface is considered to be in topographical aspects, while surface treatment methods alter both the topography and chemistry of an implant surface [6]. An acid etched surface was reported to show four times greater resistance to removal torque, the measurement of which has been one of the tools evaluating the quality of binding at the interface between the bone and the implant surface[22]. It includes Higher adhesion and expression of platelet and extracellular genes even which helps in colonization of osteoblasts at the site and promote osseointegration. Acid-etching can lead to hydrogen embrittlement of the titanium, creating micro cracks on its surface that could reduce the fatigue resistance of the implants.[23] This hydrogen embrittlement of titanium is also associated with the formation of a brittle hybrid phase, leading to a reduction in the ductility of the titanium wich is related to the occurrence of fracture in dental implants [24]. Acid etching – to create a new titanium surface combining all the aforementioned surface texture features. The present study showed that precise acid selection and the sequence of processing played the main role in preparation of the rough titanium surface. The surface was poorer if it was etched with hydrochloric acid and then with sulphuric one. The very similar results were demonstrated processing implants only with hydrochloric acid or with sulphuric/hydrochloric acids and phosphoric one. Sulphuric and hydrochloric acids in sequence and time showed the best results. The newly created titanium surface according its topography was very much alike to a SLA surface. It combines the main properties of roughened titanium surface: glossily micro rough and large waviness. In general, the experimental surface was rougher when compared tocommercially available implants. Although the implant surface created using specific acid etching methods resembles an SLA created surface, further research is necessary to study the biological response to it. Characteristics of titanium implantsurfaces have been modified by additive methods(e.g. titanium plasma spray) to increase the surface area and provide a more complex surface macro-topography. Subtractive methods(e.g. blasting, acid etching) have also been used to increase the surface area and to alter its micro-topography or texture

Electrochemical Anodization

Another method that has been shown to increase surface microtexture and change surface chemistry is electrochemical anodization. The combination of potentiostatic or galvanostatic anodization of titanium in strong acids at high current density or potential, results in thickening

of the titanium oxide layer. Anodized surfaces interfere positively in bone response with higher values for biomechanical and histomorphometric tests when compared to machined surfaces [26,27]. In electro-polishing technique, a controlled dissolution of the surface takes place under the influence of electrochemical reaction. Choice of the electrolyte is generally a mixture of an acid and alcohols. Anodization of titanium surfaces at high voltages causes crystallization of surface oxide and there by produces desired roughness and porosity. In anodic oxidation electrode reactions in combination with electrical-field driven by metal and oxygen ion diffusion lead to the formation of an oxide film at the anode surface. When anodizing process is carried out below 100 V in sulfuric acid, phosphoric acid, or acetic acid, it produces microporous surfaces [28,29]. This process is used to produce Nanoporous. This electrochemical process results in an increased thickness and modified crystalline structure of the titanium oxide layer. However, it is a complex procedure and depends on various parameters such as current density, concentration of acids, composition and electrolyte temperature [30].

Calcium Phosphate Coatings

Calcium phosphate (CaP) coatings, mainly composed by hydroxyapatite, has been used as a biocompatible, osteoconductive and resorbable blasting materials [31] The idea behind the clinical use of hydroxyapatite is to use a compound with a similar chemical composition as the mineral phase of the bone in order to avoid connective tissue encapsulation and promote peri-implant bone apposition [32]. For this matter, the CaP coatings disclose osteoconductive properties allowing for the formation of bone on its surface by attachment, migration, differentiation and proliferation of bone-forming cells. the release of calcium phosphate into the peri-implant region increases the saturation of body fluids and precipitates a biological apatite onto the surface of the implant [33].This layer of biological apatite might contain endogenous proteins and serve as a matrix for osteogenic cell attachment and growth [34] and therefore, improve osteointegration. Plasma Sprayed Hydroxyapatite (PSHA) coatings are the most commonly found among the commercially available calcium phosphate coatings. The HA ceramic particles are heated to extremely high temperatures and deposited at a high velocity onto the metal surface where they condense and fuse together forming a 20–50 µm thick film. [35]

Laser Treatment

Implant surface roughening using the previously discussed methods would cause surface contamination. Laser techniques have recently been developed as an alternative to these techniques. Laser enables implant surface treatment without direct contact and provides better control Surface Roughness of Implants.Laser treatments are clean and easy method to perform. The average surface roughness of the laser treated acid-etched implant was 2.28 ìm [36].

Conclusion

Various Methods discussed in this review are well established and are widely used by the manufacturers of current day dental implants. Although these methods have been successfully developed and employed to produce varying surface topographies, the effect of the surface topographies on the long term biological compatibility and osseointegration has not been established very well. However, research in these area are very much active and several new technologies and methods will be introduced in future to produce various surface topographies on the implants surfaces.

Abstract

In some cases, bacteria in the mouth may trigger endocarditis in people at higher risk. Bacteria found in tooth plaque may multiply and cause gingivitis (gum disease).When gums bleed, the bacteria can enter the bloodstream and can infect other parts of the body. In the case of endocarditis, this affects the inner lining of the heart and the surfaces of its valves. During dental procedures, bacteria may involve manipulation of gingival tissue (around bone and teeth) or the periapical region of teeth (tip of the tooth root).As few studies have already been reported in this topic, we have further more elucidated the importance of dental procedure on infective endocarditis patients .

Key Words: Infective endocarditis, Bacteraemia, Blood stream, Staphylococci, FimA.

Introduction

Infective endocarditis (IE) is commonly a disorder analysis that is resolved based on the nearness of various discoveries as opposed to a solitary conclusive test outcome. Despite the fact that the nearness of IE might be clear when a patient with inclining heart injuries has bacteraemia without an undeniable source, it is frequently a troublesome finding to set up in different patients who are found in routine clinical practice[1]. At the point when the highlights of IE are atypical or conceal by existing together infections, misdiagnosis may prompt clinical disaster. Then again, finished finding of IE may prompt various iatrogenic issues emerging from antimicrobial treatment or its simultaneous vascular access.

Infective endocarditis is a genuine contamination happening on the endothelial surfaces of the heart, particularly at the valves.It is a perilous disease[2].It is constantly lethal if untreated, and it keeps on causing considerable horribleness and mortality regardless of present day antimicrobial and surgical treatments.oral microscopic organisms are most imperative etiological factor in this disease.Common dental procedures,even non-surgical dental methods, can frequently cause bacteraemia of oral commensals.scaling,gingivectomy, dental water system, brushing the teeth likewise instigates bacteraemia.Periodontally sick patients are in danger from bacteraemia even in the wake of brushing the teeth.Infective endocarditis happens in 3 conditions,1) inclining weaknesses in the heart, 2) presentation of microorganisms into the circulation system ,3) harmfulness of bacteria.Antibiotics must be sufficiently used to keep this infection.Antibiotic prophylaxis ought to be given before dental procedure[3].

Infective Endocarditis

Infective endocarditis (IE) is characterized as a disease of the endocardial surface of the heart , which may incorporate at least one heart valves, the painting endocardium, or a septal deformity. Its intracardiac impacts incorporate extreme valvular deficiency, which may prompt obstinate congestive heart disappointment and myocardial abscesses[4].Fungi,chlamydia,rickettsia can cause contamination, however most regular reason for this sickness are microscopic organisms, so they are additionally called bacterial endocarditis.According to common history of ailment, it has been grouped in to intense and subacutetypes.It has been arranged in to prosthetic valve endocarditis and local valve

endocarditis related with valve replacement.It can likewise be named intravenous medication mishandle endocarditis and nosocomial endocarditis related with intravenous catheters[5].

The rate of IE runs starting with one nation then onto the next inside 3– 10 scenes/100 000 man years. This may reflect methodological contrasts between studies instead of genuine variety. Of note, in one studies, the rate of IE was low in youthful patients however expanded drastically with age—the pinnacle rate was 14.5 scenes/100 000 man a long time in patients in the vicinity of 70 and 80 years of age[6]. In every epidemiological investigation of IE, the male:female proportion is ≥2:1, in spite of the fact that this higher extent of men is inadequately comprehended. Moreover, female patients may have a more terrible anticipation and experience valve surgery less as often as possible than their male counterparts[7].

Pathophysiology

Infective endocarditis grows most usually on the mitral valve, once in a while on the aortic valve, the consolidated mitral and aortic valve, the tricuspid valve, and, infrequently, the pulmonic valve.IE creates from basic process,1) Bacteraemia that conveys the living beings to the surface of the valve,2)Adherence of the organisms,3)Eventual attack of the valvular pamphlets. IE comes about because of adherence of microorganisms to injured cardiovascular surfaces and their multiplication at the adjacentsite.Damaged heart valves as a sequela of rheumatic fever or past endocarditis, obtained valve injuries, roughened heart surfaces because of-fly stream impact from blood crossing innate cardiovascular sores, for example, septal imperfection, and prosthetic heart valve are the typical inclining condition for infective endocarditis sterile vegetations made out of platelet-fibrin cluster and thrombus are at first framed on harmed endothelial surfaces, at that point microscopic organisms are acquainted in with blood stream[8].Subsequent development of the infective vegetation causes nearby myocardial sore, that restrains valvular capacity and it brings about congestive heart disappointment.

The advancement of IE is the net consequence of the unpredictable collaboration between the circulation system pathogen with framework atoms and platelets at locales of endocardial cell harm. What's more, a significant number of the clinical indications of IE exude from the host's resistant reaction to the tainting microorganism[9]. The accompanying succession of occasions is thought to bring about IE: development of nonbacterial thrombotic endocarditis

(NBTE) on the surface of a heart valve or somewhere else that endothelial harm happens, bacteraemia, adherence of the microscopic organisms in the circulatory system to NBTE, and multiplication of microorganisms inside a vegetation.

Formation of NBTE

Turbulent blood stream delivered by specific kinds of innate or obtained coronary illness, for example, spill out of a high-to a low-weight chamber or over a limited opening, damages the endothelium. This makes an inclination for statement of platelets and fibrin on the surface of the endothelium, which brings about NBTE. Attack of the circulation system with a microbial animal categories that has the pathogenic potential to colonise this site would then be able to bring about IE.

Transient Bacteraemia

Mucosal surfaces are populated by a thick endogenous microflora. Injury to a mucosal surface, especially the gingival cleft around teeth, oropharynx, GI tract, urethra, and vagina, discharges a wide range of microbial species temporarily into the circulation system. Transient bacteraemia caused by viridian assemble streptococci and other oral microflora happens usually in relationship with dental extractions or other dental methods or with routine every day activities[10]. Albeit dubious, the recurrence and power of the subsequent bacteraemia are accepted to be identified with the nature and size of the tissue injury, the thickness of the microbial vegetation, and the level of irritation or disease at the site of injury. The microbial species entering the course relies upon the extraordinary endogenous microflora that settlements the specific damaged site.

Bacterial Adherence

The capacity of different microbial species to hold fast to particular destinations decides the anatomic localisation of contamination caused by these microorganisms. Middle people of bacterial adherence fill in as harmfulness factors in the pathogenesis of IE. Various bacterial surface parts introduce in streptococci, staphylococci, and enterococci have been appeared in creature models of test endocarditis to work as basic attachments. Some viridian aggregate streptococci contain a FimA protein that is a lipoprotein receptor antigen I (LraI) that fills in as a noteworthy bond to the fibrin platelet lattice of NBTE. Staphylococcal bonds work in no less than 2 ways. In one, microbial surface parts perceiving cement lattice atoms encourage

the connection of staphylococci to human extracellular grid proteins and to restorative gadgets that wind up covered with network proteins after implantation[11]. In the other, bacterial extracellular structures add to the arrangement of biofilm that structures on the surface of embedded restorative gadgets. In the two cases, staphylococcal bonds are imperative destructiveness factors.

Both FimA and staphylococcal grips are immunogenic in exploratory diseases. Antibodies arranged against FimA and staphylococcal bonds give some defensive impact in trial endocarditis caused by viridian assemble streptococci and staphylococci[12].The consequences of these exploratory examinations are very captivating, in light of the fact that the advancement of a successful immunisation for use in people to anticipate viridian gather streptococcal or staphylococcal IE would be of real significance.

Multiplication of Bacteria Within a Vegetation

Microorganisms follower to the vegetation invigorate promote statement of fibrin and platelets on their surface. Inside this segregated concentration, the covered microorganisms duplicate as quickly as microscopic organisms in stock societies to achieve maximal microbial densities of 108 to 1011 province shaping units for each gram of vegetation inside a brief timeframe on the left half of the heart, evidently uninhibited by have guards in left-sided lesions[13]. Right-sided vegetations have bring down bacterial densities, which might be the result of host barrier components dynamic at this site, for example, polymorphonuclear action or platelet-determined antibacterial proteins. Over 90% of the microorganisms in develop left-or right-sided valvularvegetations are metabolically dormant as opposed to in a dynamic development stage and are in this manner less receptive to the bactericidal impacts of anti-infection agents.

Dental Techniques and Infective Endocarditis

The circulatory system is clean under typical solid condition.The presentation of microscopic organisms into the circulation system is vital for an intra heart contamination to occur.Such bacteraemia happens after tooth extractions and other oral surgery procedures.Non surgical dental techniques, for example, organization of nearby anaesthesia, orthodontic band position, periodontal testing, dental prophylaxis, scaling, root arranging and even after tooth brushing and flossing. Most mash and periapical ailment is caused by microbial infection[14].

Agent techniques for its administration run from straightforward mash topping, through traditionalist root channel treatment to crisis seepage and surgical endodontics. Practically speaking, any of these mediations and their aides including neighbourhood analgesic organization and elastic dam arrangement including contaminated tissues are equipped for inciting bacteraemia and setting patients in danger of infective endocarditis. Bacteraemia does not happen or is a phenomenal and fleeting occasion following pulpotomy or root channel preparation short of root-apex[15]. Contemporary examinations utilizing thorough microbiological methods have yielded more positive blood societies, and even the utilization of rubber dam was as of late appeared in kids to deliver bacteraemia of practically identical extent to a dental extraction[16]. Profoundly delicate, sub-atomic strategies presently can't seem to be connected in the distinguishing proof and sourcing of cultivable and non-cultivable organisms in the dissemination after cautious endodontic treatment. It is likely that a wide assortment of creatures would be identified, however their importance as for infective endocarditis isn't known. It might create the impression that endodontics as a hazard factor for IE relies on the idea of instrumentation, including the think or unintentional expansion of instruments past the root end. More obtrusive, surgical endodontic strategies with fold withdrawal and periapical curettage are related typically with a high predominance of bacteraemia[17].

Periodontitis and Infective Endocarditis

Bacteraemia is all the more habitually inducible in patients with serious periodontal maladies than the individuals who have more beneficial periodontal tissue after tooth brushing and periodontal pocket probing.Gum irritation extricates the gingival epithelial tissues and it regularly end up ulcerative at inward piece of periodontal pockets. It can give oral microscopic organisms the course to getting in to the circulation.Periodontopathic microorganisms, for example, An actinomycetemcomitans and P gingivalis have the ability to attack the host epithelial and connective tissues, brings about augmentation of incendiary sore [18].Periodontopathic microbes which assume a critical part in acceptance of IE by causing gum aggravation and opening a course toward the blood dissemination for endocardopathic viridian streptococci.

Counteractive Action of Infective Endocarditis

It has for some time been exhorted that Antibiotic prophylaxis is required before dental techniques prone to create a bacteraemia in view of the high bleakness and mortality identified with IE. Two systems are believed to be included. Initial, a diminishment in the quantity of life forms in the blood and second, a decrease in the bond of living beings to the nonbacterial thrombotic vegetation.cephalaxine and cefadoxil can be utilized for patients with history of penicillin hypersensitivity, yet the utilization of beta lactate operators for patients with penicillin sensitivity might be addressed, different specialists, for example, clindamycin,azithromycin,clarithromycin ought to be prescribed. Notwithstanding anti-toxin prophylaxis of IE, different techniques for lessening bacteraemia from an oral root have been looked for. The utilization of pre-surgical 1% povidone-iodine has been shown to cause noteworthy lessening in bacteraemia from oral sources ,albeit routine utilise may incite the choice of safe microorganisms[19].

The rule of prophylaxis for IE was produced based on observational examinations in the mid twentieth century[20]. The essential speculation depends on the presumption that bacteraemia consequent to therapeutic systems can cause IE, especially in patients with inclining factors, and that prophylactic anti-infection agents can anticipate IE in these patients by limiting or forestalling bacteraemia, or by changing bacterial properties prompting decreased bacterial adherence on the endothelial surface. The suggestions for prophylaxis are situated to some degree on the consequences of creature thinks about demonstrating that anti-microbial could keep the advancement of test IE after vaccination of microscopic organisms.

Standards of the New ESC Guidelines

Recent guidelines proposed impediment of prophylaxis to patients at expanded danger of unfriendly result of IE or even entire discontinuance of anti-infection prophylaxis in any patient gatherings, the Task Force decided[21]:

– to maintain the principle of antibiotic prophylaxis when performing procedures at risk of IE in patients with predisposing cardiac conditions, *but*

– to limit its indication to patients with the highest risk of IE (*Table 1*) undergoing the highest risk procedures (*Table 2*).

Table 1: Cardiac conditions at highest risk of infective endocarditis for which prophylaxis is recommended when a high risk procedure is performed

RECOMMENDATIONS: PROPHYLAXIS	CLASS [a]	LEVEL[b]
Antibiotic prophylaxis should only be considered for patients at higher risk of IE 1.Patients with prosthetic valve or prosthetic materials used for cardiac valve repair. 2. Patients with previous IE 3. Patient with congenital heart disease	II_a	C
Antibiotic prophylaxis is no longer recommended in other forms of valvular or congenital heart disease	III	C

[a]Class of recommendation.

[b]Level of evidence.

Table 2: Recommendations for prophylaxis of infective endocarditis in highest risk patients according to the type of procedure at risk

Recommendations : prophylaxis	Class[a]	Level[b]
A - Dental procedure Antibiotic prophylaxis should only be considered for dental procedures requiring manipulation of the gingival or periapical region of tooth or perforation of oral mucosa	II_a	C
Antibiotic prophylaxis is not recommended for LA injections in non infected tissue, removal of sutures, dental X-rays, placement or	III	C

adjustment of removable prosthesis or orthodontic appliances or braces.		
B – Respiratory tract procedures* Antibiotic prophylaxis is not recommended for respiratory tract procedures, including bronchoscopy or laryngoscopy, transnasal or endotracheal intubation.	III	C
C – Gastrointestinal or urogenital procedures* Antibiotic prophylaxis is not recommended for gastroscopy, colonoscopy, cystoscopy or transoesophageal echocardiography.	III	C
D – Skin and soft tissues* Antibiotic prophylaxis is not recommended for any procedures	III	C

[a]Class of recommendation.

[b]Level of evidence.

*For management when infections are present.

1**. Patients with the Most Elevated Danger of Infective Endocarditis** (Table 1)

They incorporate three classes of patients:Although AHA rules suggest prophylaxis in cardiovascular transplant beneficiaries who create heart valvulopathy, this isn't upheld by solid confirmation. What's more, in spite of the fact that the danger of unfriendly result is high when IE happens in transplant patients, the likelihood of IE from dental starting point is

to a great degree low in these patients.The ESC Task Force does not suggest prophylaxis in such circumstances.

a. Patients with a prosthetic valve or a prosthetic material utilized for heart valve repair: these patients have a higher danger of IE, a higher mortality from IE and more regularly create intricacies of the sickness than patients with local valves and an indistinguishable pathogen.

b. Patients with past IE: they likewise have a more serious danger of new IE, higher mortality and rate of confusions than patients with a first scene of IE.

c. Patients with intrinsic coronary illness (CHD), specifically those with complex cyanotic coronary illness and the individuals who have post-agent palliative shunts, courses, or different prostheses. After surgical repair with no leftover imperfections, the Task Force suggests prophylaxis for the initial a half year after the method until the point when endothelialization of the prosthetic material happens.

Prophylaxis isn't suggested for some other type of local valve infection (counting the most generally distinguished conditions, bicuspid aortic valve, mitral valve prolapse, and calcific aortic stenosis).

2. **Most Astounding Danger Strategies**(Table 2)

a. **Dental Strategies**

Strategies in danger include the control of the gingival or periapical district of teeth or aperture of the oral mucosa (counting scaling and root channel methodology). Prophylaxis should just be considered for patients depicted in Table 1 experiencing any of these methods, and isn't prescribed in different circumstances. The fundamental focuses for anti-toxin prophylaxis in these patients are oral streptococci. Table 2 abridges the primary regimens of anti-microbial prophylaxis prescribed before dental methods. The effect of expanding protection of these pathogens for the adequacy of anti-microbial prophylaxis is indistinct.

Fluoroquinolones and glycopeptides are not prescribed because of their vague viability and the potential enlistment of protection.

b. **Other In Danger Methods**

There is no convincing proof that bacteraemia coming about because of either respiratory tract techniques, gastrointestinal or genitorurinary systems, dermatological or musculoskeletal methodology cause IE[22]. Subsequently, prophylaxis isn't prescribed in patients experiencing these systems.

Respiratory Tract Methodology

Patients recorded in Table 1 who experience an obtrusive respiratory tract methodology to treat a built up contamination, e.g. seepage of a canker, ought to get an anti-toxin regimen which contains an against staphylococcal penicillin or cephalosporin. Vancomycin ought to be given to patients unfit to endure a β-lactam. Vancomycin or another appropriate specialist ought to be managed if the disease is known or suspected to be caused by a methicillin-safe strain of S. aureus (MRSA).

Gastrointestinal or Genitourinary Methods

On account of a set up disease or if anti-infection treatment is demonstrated to forestall wound contamination or sepsis related with a gastrointestinal or genitourinary tract strategy in patients portrayed in Table 1, it is sensible that the anti-microbial regimen incorporates a specialist dynamic against enterococci, e.g. ampicillin, amoxicillin, or vancomycin. Vancomycin should just be regulated to patients unfit to endure β-lactams. On the off chance that contamination is caused by a known or associated strain with safe enterococcus, conference with an irresistible infections expert is recommended[23].

Dermatological or Musculoskeletal Methods

For patients depicted in Table 1 experiencing surgical methods including tainted skin (counting oral abscesses), skin structure, or musculoskeletal tissue, it is sensible that the restorative regimen contains an operator dynamic against staphylococci and β-haemolytic streptococci, e.g. an against staphylococcal penicillin or cephalosporin. Vancomycin or clindamycin might be utilized as a part of patients unfit to endure a β-lactam. On the off chance that the disease is known or suspected to be caused by MRSA, vancomycin or another reasonable specialist ought to be directed.

Body Puncturing and Inking

These developing social patterns are a reason for concern, especially for those people with CHD who are at expanded defencelessness for the procurement of IE. Case reports of IE in the wake of penetrating and inking are expanding, especially while puncturing includes the tongue, in spite of the fact that production inclination may overestimate the issue since a large number of individuals are inked and penetrated far and wide and CHD concerns just 1% of the overall public. Right now no information are accessible on (a) the frequency of IE after such strategies and (b) the adequacy of anti-microbials for counteractive action. Training of patients in danger of IE is fundamental, and penetrating and inking techniques ought to be demoralized. On the off chance that attempted, strategies ought to be performed under entirely sterile conditions however anti-infection prophylaxis isn't recommended[24].

Heart or Vascular Surgery

In patients experiencing implantation of a prosthetic valve or intravascular prosthetic or other remote material, peri-agent anti-microbial prophylaxis ought to be considered because of the expanded hazard and unfavourable result of a contamination. The most regular microorganisms hidden early (<1 year after surgery) prosthetic valve diseases are CNS and S. aureus. Prophylaxis ought to be begun instantly before the methodology, rehashed if the strategy is drawn out, and ended 48 h subsequently. It is firmly prescribed that potential wellsprings of dental sepsis are wiped out no less than 2 weeks before implantation of a prosthetic valve or other intracardiac or intravascular remote material, unless the last technique is critical.

Methods Causing Medicinal Services Related IE

They speak to up to 30% of all instances of IE and are portrayed by an expanding frequency and a serious guess, subsequently speaking to a critical medical issue. Albeit routine antimicrobial prophylaxis directed before most intrusive strategies isn't prescribed, aseptic measures amid the inclusion and control of venous catheters and amid any obtrusive techniques are obligatory to diminish the rate of this disease.

1. Blood Culture

Positive blood societies remain the foundations of analysis and give live microscopic organisms to powerlessness testing. Three sets (counting no less than one high-impact and

one anaerobic), each containing 10 mL of blood acquired from a fringe vein utilizing fastidious sterile strategy, is for all intents and purposes constantly adequate to recognise the standard microorganisms—the analytic yield of rehashed testing from there on is low. Inspecting from focal venous catheters ought to be evaded in perspective of the high danger of contaminants (false positives, ordinarily staphylococcal) and deluding discoveries. The requirement for culture before anti-infection organization is plainly obvious, despite the fact that studies of contemporary practice uncover visit infringement of this run the show. In IE, bacteraemia is relatively consistent, which has two ramifications: (1) there is no justification for postponing blood testing to harmonise with pinnacles of fever; and (2) for all intents and purposes all blood societies (or a greater part of them) are certain. Accordingly, a solitary positive blood culture ought to be respected carefully to establish the conclusion of IE, particularly for conceivably 'contaminants, for example, CNS or corynebacteria.

Albeit IE caused by anaerobes is phenomenal, societies ought to be hatched in both oxygen consuming and anaerobic environments to distinguish living beings, for example, Bacteroides or Clostridium species. At the point when societies stay negative at 5 days, subculture onto chocolate agar plates may permit ID of an exacting life form. Drawn out culture is related with rising probability of pollution, and elective procedures (or an elective determination) ought to be considered at this stage.

2.Histological/Immunological Strategies

Obsessive examination of resected valvular tissue or embolic pieces remains the best quality level for the determination of IE and may likewise control antimicrobial treatment if the causative operator can be recognised by methods for extraordinary stains or immunohistological systems. Electron microscopy has high affectability and may describe new microorganisms, yet is tedious and costly. Coxiellaburnetii and Bartonella species might be effortlessly identified by serological testing utilizing backhanded immunofluorescence or chemical connected immunosorbent examine (ELISA), and late information exhibit comparable utility for staphylococci. Immunological examination of pee may permit location of microorganism corruption items, and ELISA discovery of Legionella species has been portrayed utilizing this technique[25]. Joining of these strategies into acknowledged symptomatic criteria anticipates planned approval.

Treatment for Infective Endocarditis

Staphylococcal Endocarditis

Intravenous treatment for a month is suggested for staphylococcal NVE, which ought to be stretched out to no less than a month and a half in patients with intracardiacprostheses[26,27].

NVE, methicillin-safe: vancomycin AND rifampicin.

NVE, methicillin-safe, vancomycin-safe: daptomycin AND rifampicin OR gentamicin.

PVE, methicillin, rifampicin-powerless staphylococci: flucloxacillin AND rifampicin AND gentamicin.

PVE, methicillin-safe, vancomycin-powerless or penicillin sensitivity: vancomycin AND rifampicin AND gentamicin.

PVE, methicillin-safe, vancomycin-safe: daptomycin AND rifampicin AND gentamicin.

Streptococcal Endocarditis

Benzylpenicillinmonotherapy; ceftriaxone monotherapy; benzylpenicillin AND gentamicin; ceftriaxone AND gentamicin.Treatment of streptococci in patients with hugepenicillin allergy: vancomycin AND gentamicin; teicoplanin AND gentamicin.

Enterococcal Endocarditis

Amoxicillin OR penicillin AND gentamicin; vancomycin AND gentamicin; teicoplanin AND gentamicin; amoxicillin (for amoxicillin-helpless AND abnormal state gentamicin safe disconnects).

Parasitic Endocarditis

Against parasitic operators utilized incorporate fluconazole, voriconazole, amphotericin, micafungin, caspofungin, anidulafungin, posaconazole and flucytosine. Itraconazole ought not be utilized.

CandidalEndocarditis

Starting treatment ought to be with an echinocandin or amphotericin. Surgical valve substitution is suggested.

Conclusion

Regular dental methods, even non-surgical dental techniques, frequently cause bacteraemia that can bring about infective endocarditis in individuals who have an inclining hazard for this illness, for example, valvular heart ailments including prosthetic valve, inborn heart diseases,cardiomyopathy,coronary course malady, pacemaker implantation etc.Common dental methodology frequently cause bacteraemia and periodontally unhealthy patients may significantly experience the ill effects of bacteraemia after tooth brushing.Antibiotics must be utilized sufficiently so as to avert such contaminations amid dental systems.

Abstract

The single enantiomers are considered to be safer and better alternatives to racemates, has resulted in a need for developing single isomers as drug products. Most of the drugs in use today are chiral. It is well established that the pharmacological activity is mostly restricted to one of the enantiomers and the individual enantiomers of racemic drugs frequently differ in their biological effects. In many cases, the inactive enantiomer shows unwanted side effects or even toxic effects. A pharmacological study reveals that there is a need for separating and quantifying enantiomers in biological samples to assess the toxic effects of such drugs. Single enantiomer products are being re-marketed by so called the chiral switch process. (Racemate to single enantiomer).Therefore, it is important to promote the chiral separation and analysis of racemic drugs in pharmaceutical industry as well as in clinic in order to eliminate the unwanted isomer from the preparation and to find an optimal treatment and a right therapeutic control for the patient. In this article, we review the nomenclature, pharmacology, toxicology, pharmacokinetics, metabolism etc of some usual chiral drugs as well as their mechanisms. Different techniques used for the chiral separation in pharmaceutical industry as well as in clinical analyses are also examined.About more than half of the drugs currently in use are chiral compounds and near 90% of the last ones are marketed as racemates consisting of an equimolar mixture of two enantiomers. Although they have the same chemical structure, most isomers of chiral drugs exhibit marked differences in biological activities such as pharmacology, toxicology, pharmacokinetics, metabolism etc. Some mechanisms of these properties are also explained.

KeyWords: *enantiomers, chiral drug, thalidomide, stereoisomers, pharmacology, enantioselective*

Introduction

Enantiomers chemistry was discovered by Louis Pasteur, a French chemist and biologist, when he separated by hand for the first time, in 1848, the two isomers of sodium ammonium tartrate. However, it needed about a century later to find that the phenomenon of chirality plays a key role not only in the life of plants and animals but also in pharmaceutical, agricultural and other chemical industries. All proteins, enzymes, amino acids, carbohydrates, nucleosides and a number of alkaloids and hormones are chiral compounds. In pharmaceutical industries, 56% of the drugs currently in use are chiral products and 88% of the last ones are marketed as racemates consisting of an equimolar mixture of two enantiomers (1). In contrast to chiral artificial products, all natural compounds are under single enantiomeric form, for example, all natural amino acids are l-isomer (levorotatory) as well as all natural sugars (carbohydrates) are d-isomer (dextrorotatory). Although they have the same chemical structure, most enantiomers of racemic drugs exhibit marked differences in biological activities such as pharmacology, toxicology, pharmacokinetics, metabolism etc. The mechanisms of chiral drugs with biological environment are now explained. Therefore, it is important to promote the chiral separation and analysis of racemic drugs in pharmaceutical industry as well as in clinic in order to eliminate the unwanted isomer from the preparation and to find an optimal treatment and a right therapeutic control for the patient (2).

An enantiomer is one of two stereoisomers that are mirror image of each other that are non-identical. Their isomers have the same chemical formula but with different orientations of the side groups around the central atom. They share the same chemical and physical properties, the same chemical formula, the same bond angles, the same boiling point, and the same melting point. In fact, their only difference lies in the direction in which they rotate polarized light, which are dextrorotary (clockwise rotation) and levorotary (counterclockwise rotation). (3) Due to these changes, sometimes only one of the enantiomers have a therapeutic effect while the other may have an entirely different effect, no effect at all, or even have undesired side effects. Our body

can only recognize one enantiomer which in result producing therapeutic effect. This will bind along with its chiral receptor whereas another enantiomer disturbs the metabolic and regulation process and causes side effect.This problem has been overcome with the production of single enantiomer drug.

Enantiomer was a top-class subject for academic research as well as for pharmaceutical development. Accounting for the important role of enantiomers separation, the 2001 Nobel Prize in Chemistry has been awarded to three scientists, Dr. William S. Knowles and Pr. K. Barry Sharpless in USA and Pr. RyoriNyori in Japan, for their development of asymmetric synthesis using chiral catalysts in the production of single enantiomer drugs or chemicals. Thanks to a wide range of new technologies for enantiomers separation, US Food and Drug Administration (FDA) recently recommends the assessments of each enantiomer activity for racemic drugs in body and promotes the development of new chiral drugs as single enantiomers(3).

Few separation techniques are introduced and single enantiomer is formulated. Examples of single enantiomer drug used clinically nowadays are omeprazole, propranolol, albuterol etc.In many cases, one enantiomer is the active pharmaceutical ingredient while the other can be benign or even toxic. Thalidomide racemate was one of the first drugs recognized to cause birth defects in humans, which is due to (-)(S)thalidomide. It causes severe side-effects and thousands of babies were born with missing or abnormal arms, hands, legs, or feet. One side of the drug is known to efficacy whereas the other is the cause of side effect which causes teratogenic effect. As the next step in newer generation the scientists introduces the separation technique to prevent the side effects. Here is where the single enantiomers is introduced commercially. Only single-enantiomers are provided in market nowadays. (5)

In this article, we review the nomenclature of chiral compounds, the biological activities such as pharmacology, toxicology, pharmacokinetics, metabolism etc of some usual racemic drugs in therapeutics as well as their mechanisms. Different techniques used for the chiral separation in pharmaceutical industry as well as in clinical analyses are also examined

History of Enantiomers

Previously, all drugs were made from racemic mixtures or mixtures with equal amounts of both enantiomers. Separation of the two enantiomers thought to be unnecessary due to its high cost. Therefore, enantiomer drugs were given to patients without purification. In 1960s, to inhibit the effects of morning sickness in pregnant woman the drug named Thalidomide is introduced. It is a racemic mixture composed of both R-thalidomide and S-thalidomide. As a result after its release, over 10,000 children of women using this drug were born with severe birth defects such as phocomelia, the development of flipper-like limbs.(6)

Consequently, Thalidomide was sealed as one of the most severe pharmaceutical failures of the 20th century. Research is quickly done by scientists but it was fiasco. However within a few years, scientists discovered the cause of the fatal flaw, it was the nature of enantiomers which was far more complex than ever imagined. The R-form of the enantiomer showed the reputed characteristic of inhibiting morning sickness. It seemed effective in preventing morning sickness and producing desired results. However, the S-form of the organic compound thalidomide produced teratogenic effects which caused the fatal defects in embryonic formation. (7) These effects were believed to result from the increased affinity of S-thalidomide with embryonic cerebrum proteins, which have a direct effect on limb formation. The Thalidomide incident had invested greater interest in a previously recondite and unknown region of the enantiomers.

Pharmaceutical expects spent much of their resources developing better techniques to separate enantiomers in the process of forming aenantiopure drug. Various techniqueswere experimented to separate enantiomers. However the first successful method which is reproducible in separation process was the gas chromatograph, was done in 1966 using an isoleucine lauryl ester mixture as the stationary phase for separating two amino acid enantiomers. Once the racemic mixture was separated into enantiopure mixtures, the optical purity, or the ratio of the two enantiomers, was measured to determine the efficacy of the separating process. (8)

Pharmacology of Enantiomers

Enantiomers (also sometimes called stereoisomerism or chirality or dissymmetry) are a property of an object which is non-superimposable with its mirror image. When a molecule cannot be superimposed on its mirror image, this molecule and its image are called chiral. It is like left and

right hands. The two non-superimposable mirror-image forms of chiral molecules are called enantiomers. Enantiomers are most commonly formed when a carbon atom contains four different substituents (asymmetric carbon atom or stereogenic carbon or also called chiral center). A chiral molecule is a molecule having at least one asymmetric carbon. Carbon is not the only atom that can act as an asymmetric center. Sulfur, phosphorus and nitrogen can sometimes form chiral molecules such as omeprazole, cyclophosphamide and methaqualone, respectively. Chiral molecules exhibit optical activity, so enantiomers are also sometimes called optical isomers. The two enantiomers of such compounds may be classified as levorotary (l-isomer) or dextrorotary (d-isomer) depending on whether they rotate plane-polarized light in a left (-) or right (+) -handed manner, respectively. An equimolar mixture (50/50) of the two enantiomers of a chiral compound is called a racemic mixture (racemate) with sign (±) or (d, l) that does not exhibit optical activity. Optical isomers or enantiomers are molecules having the same chemical formula, the same physical and chemical properties, but differing in their optical activity and their spatial arrangement.

Enantiomers are now determined by their spatial arrangement (3 dimensions) of substituents (groups) around a chiral center (asymmetric carbon) in the molecule. This configuration follows the Cahn-Ingold-Prelog (CIP) convention which is used to assign priorities to substituent groups. This system is based on a set of rules for ordering the substituents attached to the asymmetric atom by using sequence rules to assign priorities. The spatial arrangement of a chiral compound is determined by nuclear magnetic resonance or/and X-ray crystallography diffraction. The R/S tri-dimensional configuration allows explaining the interaction of enantiomers with their biologic receptors.

Diastereomers are any molecules which have two or more chiral centres. A diastereomer with two chiral carbon has four isomers. Unlike enantiomers, the physical and chemical properties of diastereomers can differ and consequently, their chemical characterization is easy and their biological activities are often different. This is the basis for derivatization of enantiomers to form diastereomers in chiral separation and also for the explanation of enantiomer activities with their chiral receptors in the body. Diastereomers, enantiomers and geometric isomers form a family called stereoisomers that are molecules having the same chemical formulas but differing only

with respect to the spatial arrangement.Eutomer refers to bioactive enantiomer or enantiomer having higher pharmacological activity. Its opposite is called distomer.Epimers are two diastereoisomers having a different configuration at only one chiral centre.

Enantioselectivity is a property of a process whereby one enantiomer is expressed exclusively or predominantly over the other. In pharmacological terms, that means a biological structure (enzyme, antibody or receptor) which exhibits affinity towards one enantiomer over the other. Enantioselective assay is an analytical method capable of separating and quantifying enantiomers.

In a stereoselective synthesis, one of a set of isomers is predominantly or exclusively formed whereas in a stereospecific synthesis, one isomer leads to one product while another isomer leads to the opposite product.Homochirality is the biological chirality in which all biologic compounds have the same chirality such as all amino acids are levorotary isomers. Chiral switch is a procedure used to transform an old racemic drug into its single active enantiomer. This new enantiomeric drug developed by a pharmaceutical manufacturer will receive additional patent protection and a new generic name. (9)

Technique Used for Separation of Enantiomers

The main techniques of enantiomer separations are capillary electrophoresis, asymmetric biotransformation, liquid-liquid extraction, membranes, sensors, chromatography and crystallization. Enantiomer separation methods, is emphasized on separation by chiral inclusion complexes and crystallization, biological methods, preparative liquid and gas chromatographic methods have been reported. Conventionally optical isomers of racemic compounds can be separated but this has always been difficult and expensive. Hence, chiral separationis usednowadays to producedual isomer recovery, as well as to generate only single-isomer recovery.

In industry, there are two main categories of techniques that are often applied for enantiomer separation, the classical methods and the modern technology.First of all the classic method, it’s the most widely used technique, is the resolution by diastereomeric salt formation. In this

method, an acid-base reaction is involved between a racemic drug and a pure single enantiomer called resolving agent. This reaction is responsible for the formation of two diastereomeric salts which have different physical and chemical properties and can be easily separated either by filtration or by crystallization if one is insoluble and the other is soluble. Finally, the pure enantiomer is obtained by salt decomposition by treatment with either acid or base. It can also be separated by classical achiral liquid chromatography. This method has been used in the resolution of -methyl-L-dopa, asparagine and glutamic acid which is widely been using clinically.[10]

Other classical method that is being used is enzymatic or kinetic resolution. In this methodology, formation of resolution is achieved with the biochemical process which destroys one enantiomeric form that causes side effect. Certain microorganisms such as yeasts, molds, bacteria can only degrade one of two isomers of a racemate by enzymatic assimilation. Whereas, the other side which is not digested remains in the solution will be isolated. Enzymatic resolution has been used in the preparation of lorafiban (benzodiazepine), levofloxacin (antibacterial drug), and S-naproxen (anti-inflammatory drug). (11)

The modern technologies, ensures the preparative high-performance liquid chromatography (HPLC) as the method of choice for the enantiomer separation. This method has proven to be one of the best methods for the direct separation and analysis of enantiomers. In chromatographic methods, indirect and direct methodologies are used. The indirect HPLC involves derivatization of samples with a chiral derivatization reagent, for an example a pure single enantiomer, resulting in the formation of two diastereomers which can be separated by a classical reversed-phase column. This indirect HPLC method is rarely used in industry, but due to its high sensitivity, it is frequently performed in biological analysis. Whereas, the direct HPLC utilizes in chiral stationary phases (CSPs) or in the mobile phase called chiral mobile phase additives (CMPA). (12)

Direct chiral separations using CSPs are more widely used and are more predictable, in mechanistic terms, than those using chiral additives in the mobile phase. Among a hundred HPLC CSPs commercially available, only some types of chiral sorbents following arepresently

the most widely used for preparative HPLC in industry. Choosing the right column for the Enantio separation of a racemic compound is difficult. The decision relies mostly on empirical data and experience. However, the understanding of the recognition mechanisms of chiral selectors with enantiomers can help the chromate graphists to resolve some problems of resolution and to economize time-consuming. (13)

According to Aboun-Enein and Ali all chiral selectors provide a chiral surface to enantiomers, which form with the selectors temporary complexes, having different bonding energies. The enantiomers differ in their binding energies because they fit differently into the chiral selector structures. Consequently, the two enantiomers can be eluted at different times by the mobile phase and then separately collected. Briefly, in general, the recognition mechanism on a chiral selector is based on a key-and-lock arrangement. However, many other factors such as mobile phase composition (pH, electrolytes, solvent nature), size and length of column, temperature, etc also play a key role for chiral resolution. (14)

There is also a new technique called simulated moving bed (SMB) chromatography is recently developed for industry. Basic concept of SMB technology is the continuous countercurrent movement of stationary and mobile phases in which the movement of a stationary phase is simulated. The small particles in this component are packed into single columns and connected to form a circle. Four external valves allow the addition and subtraction of feed and effluent. The mobile phase is pumped through the circle and when it passes the stationary phase a slight separation occurs, the less absorbable compound running in front and the more absorbable compound staying behind. When steady state is reached, the system can be operated continuously. If all flow rates and the shift time are determined correctly, raffinate and extract fractions can be withdrawn in high purity. An example of a pharmaceutical compound separated by SMB chromatography is tramadol. (16)

To avoid the racemization during chiral drug preparation, an asymmetry synthesis using chiral catalysts has been developed by W.S. Knowles, R. Noyori and K.B. Sharpless, the Nobel Prize in chemistry 2001 (17). Most of the available asymmetric chemical catalysts are organometal types including transition metals such as titanium, and noble metals such as osmium, palladium, and rhodium. Chiral catalysts are like enzymes in that both have a high degree of specificity. They allow stereospecific reactions to take place and therefore avoid the formation of racemates. L-Dopa (anti-Parkinson agent), naproxen (anti-inflammatory drug) are some examples of single enantiomer drugs produced by this catalytic asymmetric synthesis. (18)

Biological Activities of Enantiomers

The enantiomers may vary in their interactions with chiral environments such as enzymes, proteins, receptors, etc of the body. These variations may lead to differences in biological activities such as pharmacology, pharmacokinetics, metabolism, toxicity, immune response etc. Biological systems can recognize the two enantiomers as two different substances, and their interaction each other will therefore elicit different responses.

Easson and Stedman has proposed the reason for enantiomers recognition by drug receptors is a three-point interaction of the drug with the receptor site (19). In this case, one enantiomer is biologically active while the other enantiomer is not. In this case, this fitting interaction can produce an active biological effect. In addition, the inactive enantiomer cannot bind in the same way with its receptor when it rotates in space, consequently, there is no active response.

As a conclusion, the attachment of an enantiomer to the chiral receptor is similar to a hand fitting into a glove or to a key into a lock. Indeed, a right hand can only fit into a right hand glove, therefore a particular enantiomer can only fit into a receptor site having the complimentary shape. The other enantiomer will not fit, like a right hand in a left glove, but may fit into a receptor site elsewhere in the body and cause an eventual unwanted or toxic effect. On the other hand, enantiomers can show different chemical behaviour due to different chiral discrimination by diastereomeric formations with a chiral environment. (20)

Uses of Enantiomers

The enantiomers of chiral drugs are known to be exhibiting different pharmacological and pharmacokinetic activities because they interact with enzymes and receptors consisting of aminoacids andother chiral biomolecules.There are many enantiomers that are formulated as single enantiomers which having only the side of efficacy without a side effect phase.

For example,DOPA the precursor of dopamine that is effective in the treatment of Parkinson disease, was used under racemic form (d, l- dopa), but knowing to its toxicity (agranulocytosis) of d-isomer, only levoratory form called L-Dopa is being used nowadays in therapeutics. It has been renewed the interest in uses of thalidomide due to its immunomodulatory, anti-angiogenic, and anti-inflammatory effects. In addition, it has a strong inhibition in the tumor necrosis factor alpha (21).

Thalidomide has given spectacular results in the treatment of erythema nodosumleprosum, aptosis and Behcet's syndrome. Moreover, it has been assayed for organ transplantation, some autoimmune diseases such as chronic lupus erythematosus, rheumatoid arthritis, some forms of cancer, etc. Single thalidomide enantiomers and its derivative which is N-hydroxythalidomide, were also synthetized by asymmetric technique in order to study their individual biological and chemical activities (22).

(S)-albuterol is one of the single formulated enantiomer which is a selective alpha-2 adrenergic receptor agonist used in the treatments of asthma. The other example is (S)-omeperazole, the proton pump inhibitor for the treatment of gastrointestinal tract reflux[9]. Other than that, (S)-citalopram which is primarily responsible for re-uptake of serotonin and act as the antagonism. The drug that responsible for the local anesthetic effect which is (L)-propranolol is also an single formulated enantiomer. Other examples are Ethambutol for treatments of tuberculosis and Naproxen for the treatment of arthritis pain[23].

Conclusion

Drug enantiomers are widely being used clinically nowadays. Thus, the enantiomers need to undergo separation methods as this stereoisomers causes side effect which caused by the inefficacy side of the drug. The chiral separation of racemic drugs is a necessary in

pharmaceutical industry as well as in clinical therapeutics. However, the usage of a single isomer must be taken after long clinical assessments between the racemate and single enantiomer actions because in some cases, racemates have more therapeutic advantages than single isomers. It is also important to give more information about chiral drugs especially racemic form to healthcare professionals in order to help them for finding an optimal treatment and a right therapeutic control.

Abstract

Aerosol is a suspension of solid or liquid particles in air or other gaseous environment. Sources of bacterial aerosols exist within and outside the dental clinic. The generation of bacterial aerosols and splatters appears to be highest during dental procedures. The use of rotary dental and surgical instruments and air-water syringes generates visible infectious spray that encloses large-particle splatter of water, saliva, microorganisms, blood, and other debris. Air-water aerosol produced during dental treatment procedures emerges from a patient's mouth and mixes with the surrounding air, thus influencing its composition. The air contained in this space is the air breathed by both dentist and patient, its composition is extremely important as a potential threat to the dentist's health as well as to the patient and the dental assistant. From an infectious point of view, dentistry has never been safer than it is today for both patients and dental team. The aerosols and splatter generated during dental procedures have the potential to spread infection to dental personnel and other people in the dental office. While, as with all infection control procedures, it is impossible to completely eliminate the risk posed by dental aerosols, it is possible to minimize the risk with relatively simple and inexpensive precautions with immunization protocols requires attention. CDC and ADA protocol should be followed with at most consciousness to minimize the risk among the patients and the dentists.This review is done to recapitulate the formation of dental bio aerosols, its hazardous nature to the clinician, patient and the assistant and also the protective measure need to be taken against it thereby preventing it.

Key Words: Dental aerosol, splatter, dental office, infectious disease, ultra sonic scaling, pre-procedural rinses

Introduction

The spread of infection through aerosol and splatter has long been considered one of the main concerns in the dental community. Even before the discovery of specific infectious agents such as bacteria and viruses, the potential infection by the airborne route was recognized. A number of sources of bacterial aerosols exist within and outside the dental clinic. Dentists use high-energy equipment, such as drills and scalars, in the presence of bodily fluidssuch as blood, saliva and dental plaque. Thiscombination has been shown to generate aerosols of oral micro-organisms, and blood. Combined effect, referred as Bio-aerosols present a considerable microbial challenge to the patients, the dentist and nursing staff. Several infectious diseases could be transmitted to staff and patients by airborne bacterial and other contaminants in the dental clinic.

Aerosols are defined as liquid or solid particles suspended in the air by humans, animals, instruments, or machines. Bio-aerosols are aerosols consisting of particles of any kind of organism. [1,2] Aerosols, which are responsible for the transmission of airborne micro-organisms by air, consist of small particles named droplet nuclei (1–5μm) or droplets (>5μm). Splatter is usually described as a mixture of air, water and/or solid substances. Water droplets in splatter are from 50 micron to several millimeters in diameter and are visible to the naked eye. Droplets nuclei can stay airborne for hours, transport over long distances and contaminate surfaces by falling down [1] Humans generate bio-aerosols by talking, breathing, sneezing or coughing [1]. Based on the infectious status of a person, the bio-aerosols are proven to contain influenza or rhinoviruses[3,4] Mycobacterium tuberculosis [5], Staphylococcus aureus, Varicella Zoster Virus, Streptococcus species or Aspergillus species. [6] It is inferred from one of the study that the spread of aerosols was maximum at 2 feet distance in all directions irrespective of the environmental conditions. Whereas it was a minimal to negligible spread at 6 feet distance in all directions under all environmental conditions simulated. There was no color change in litmus paper after 6 feet, which indicates that the minimum safe distance that has to be followed around a dental chair is 6 feet.[7]

In this article, we review relevant literature that has addressed the presence and makeup of dental aerosols and splatter. We also assess the threats that may be inherent in this airborne material, including risk potential to patients and the dental team. We make recommendations for the control of dental aerosols and splatter.

Contents of Aerosol

The terms “aerosol” and “splatter” in the dental environment were used by Micik and colleagues [8,9] aerosols were defined as particles less than 50 micrometers in diameter. Particles of this size are small enough to stay airborne for an extended period before they settle on environmental surfaces or enter the respiratory tract. The smaller particles of an aerosol (0.5 to 10 µm in diameter) have the potential to penetrate and lodge in the smaller passages of the lungs and are thought to carry the greatest potential for transmitting infections. Splatter was defined by Micik and colleagues as airborne particles larger than 50 µm in diameter. Micik and colleagues stated that these particles behaved in a ballistic manner. This means that these particles or droplets are ejected forcibly from the operating site and arc in a trajectory similar to that of a bullet until they contact a surface or fall to the floor.

Composition of aerosols probably varies with each patient and operative site. However, it is reasonable to suppose that components of saliva, nasopharyngeal secretions, plaque, blood, tooth components and any material used in the dental procedure, such as abrasives for air polishing and air abrasion, all are present in dental aerosols. Several recent studies have analyzed the presence of blood components in dental aerosols.[10,11]

Aerosols may accommodate micro organisms like multidrug resistant Staphylococcus aureus, influenza, legionnaire’s disease, pneumonia, mumps, chicken pox, cytomegalovirus infection, hepatitis B and C virus infection, herpes simplex virus Types 1 and 2 infection, human immunodeficiency virus etc [12].They may also harbor mycotoxins, fungal cells such as molds, spores, yeasts, saliva, blood, protozoa and dead cell debris.

Dental Procedure That Generates Aerosol

The source of dental aerosol during dental procedures includes:

1. Patient

Dental aerosol can be produced from the patients. The amount of contamination of dental aerosol depends on the quality of saliva, nasal and throat secretion, blood, dental plaque, periodontal infection, blood and presence of any dental infection.[13] Therefore aerosol composition differs from patient to patient depending on the site and type of the procedure like tooth preparation and oral prophylaxis. [13, 14]

2. Dental Unit Waterline

The tubing in DUWL is constructed in such a way that, the centre of the lumen has the maximum flow of water and the periphery has the minimal flow. Reasons of contamination of DUWL may be due to narrow bore water lines, water stagnation, heating of dental chair unit, anti retraction valve failure and contamination of reservoir bottles. [15] Many environmental organisms identified in dental treatment water have been associated with opportunistic infections in hospitalized or immune compromised patients. For example, Pseudomonas species, non-tuberculous mycobacteria, and Legionella species all have been isolated from dental unit water. Legionella, the causative agent of Legionnaires' disease, may pose a particular concern, as it appears to be transmitted by inhaling aerosols or aspirating water contaminated with the bacteria. Biofilm is a community of bacterial cells and other microbes that adhere to surfaces and form a self protective slime layer. Found in virtually all places where moisture meets a suitable solid surface, biofilm can contain many types of bacteria as well as fungi, algae, protozoa, and nematodes. Although biofilm can form in all non-sterile fluid environments, dental waterlines provide particularly well-suited conditions. One article reports the death of an 82-year-old Italian woman died in February due to complications related to Legionnaires’ disease, a life-threatening type of pneumonia caused by Legionella bacteria, which she acquired while receiving dental care. In the Dimensions of Dental Hygiene Journal, [16] the elderly woman was hospitalized after becoming ill with a fever and respiratory distress.

3. Instruments

Instruments used for dental procedures includes: ultrasonic scalars, high speed hand pieces, air turbines, three in one syringes, and air water syringes. Most dental procedures that use mechanical instrumentation will produce airborne particles from the site where the instrument is used. Dental hand pieces, ultrasonic scalars, air polishers and air abrasion units produce the most visible aerosols. Each of these instruments removes material from the operative site that becomes aerosolized by the action of the rotary instrument, ultrasonic vibrations or the combined action of water sprays and compressed air. The water spray usually is the portion of the aerosol that is most visible to the naked eye and is noticed by the patient and dental personnel. One study, however, showed that when an ultrasonic scalar was used in vitro without any coolant water, there still was a large amount of aerosol and splatter formed from small amounts of liquid placed at the operative site to simulate blood and saliva.[18]

Investigations have evaluated the presence or absence of blood contamination in the aerosols produced during root planning when an ultrasonic scalar is used. [10, 11] These studies have shown that blood is present universally in ultrasonic scalar aerosols during root planning. While the presence of blood has not been directly studied, it would seem logical that blood also would be present in any dental aerosol that is produced by an instrument in a blood-contaminated field. This would include restorative procedures that extend subgingivally, as well as periodontal and oral surgery procedures.

4. Ventilation

There is little evidence that ventilation directly reduces the risk of disease transmission, but many studies suggest that insufficient ventilation increases disease transmission(19-21). Detection of pathogens in room air and buildings may suggest a possible, indirect association between ventilation and disease transmission [22] Lack of ventilation or low ventilation rateis associated with increased infection rates or outbreaks of airborne diseases. No information exists on the impact of ventilation rate on transmission of droplet-transmitted diseases. This agrees with the physics of droplet transmission, which shows that general ventilation should not affect large droplet transmission.A higher ventilation rate can provide a higher dilution capability and consequently potentially reduce the risk of airborne infections. [23]

Table1: Dental devices and procedures known to produce airborne contamination:

[13,24,25]

Ultrasonic and Sonic Scalars	Considered the greatest source of aerosol contamination; use of a high-volume evacuator will reduce the airborne contamination by more than 95 percent
Air Polishing	Bacterial counts indicate that airborne contamination is nearly equal to that of ultrasonic scalars; available suction devices will reduce airborne contamination by more than 95 percent
Air-Water Syringe	Bacterial counts indicate that airborne contamination is nearly equal to that of ultrasonic scalars; high-volume evacuator will reduce airborne bacteria by nearly 99 percent
Tooth Preparation With Air Turbine Hand piece	Minimal airborne contamination if a rubber dam is used
Tooth Preparation With Air Abrasion	Bacterial contamination is unknown; extensive contamination with abrasive particles has been shown

Susceptible Areas of Contamination

1) The dental clinician

2) The assistant

3) Patient

4) Dental instruments, dental handpieces along with burs, Ultrasonic scaler tips, Polishing cups

Risks of Aerosol Contamination

The role of the air as a carrier of infection is seen in Tuberculosis, measles, severe acute respiratory syndrome, multi-resistant Staphylococcus aureus, influenza, legionnaires disease, pneumonia, mumps, chicken pox, cytomegalovirus infection, hepatitis B and C virus infection, herpes simplex virus Types 1 and 2 infection, human immunodeficiency virus, etc. The dispersion of bacteria and viruses (reservoir being mouth with saliva, blood, sub gingival fluids, and moisture from the nasopharynx) into the air due to coughing, sneezing, general exhalation, and exacerbated by the use of the high-speed instruments such as ultrasonic scalars and hand pieces starts the chain of airborne infection. During dental treatment, several thousand droplets are aerosolized. The larger droplets fall quickly to the floor and onto other surfaces, the smaller droplets evaporate quickly, leaving dry microscopic droplet nuclei which remain suspended in the air for extended periods of time and require prolonged hours to settle down. The bacteria and viruses become highly mobile in the air and circulate from one room to another by convection currents. Microorganisms in excess of 5 times that of outdoor air are present in dental surgery units. [12]

Periodontitis is an inflammatory disease of the supporting tissue of the teeth caused by specific microorganisms or groups of specific microorganisms resulting in progressive destruction of the periodontal ligament and the alveolar bone with pocket formation, recession or both [26]. Dental plaque being the prime etiological agent comprises complexes of microorganisms, both bacterial and viral origin in the gelatinous matrix. It gets dispersed when mechanically acted upon pressure of food, friction of soft tissues or dislodgement by the ultrasonic devices [27]. Therefore the aerosols produced by ultrasonic scalar units are heavily contaminated by microorganisms which have the capability of disease transmission leading to various diseases like mild flu, pneumonia [28, 29 & 30] streptococcal and staphylococcal infections, viral infection, conjunctivitis [31], amoebic keratitis [32], tuberculosis and severe acute respiratory syndrome (SARS). Blood borne pathogens like HIV, HBV, and HCV can be transmitted through the inhalation of blood containing aerosol via the microlesion in the mucosa of the airways which acts as the potential access for such viruses. [33, 34] It can also contaminate the nearby instruments on the instrument trays which can further act as a source of infection to the patient

Contamination from dental instrumentation is the result of organisms on instruments and in DUWLs. Routine cleaning and sterilization procedures should eliminate contamination of all dental instruments except those being used with the current patient. The use of ADA-recommended methods to treat the DUWL also should minimize or eliminate airborne contamination from the DUWL, because contamination from these sources is controlled relatively easily by standard procedures.Snophia S et al, in 2011 reported two patients contaminated with Pseudomonas Aerugiosa when treated in a dental clinic, where DUWL was the source of infection. The microorganism which was isolated from the oral abscess developed in these patients was the same strain isolated from the DUWL [35]. Other respiratory infections reported were mild flu and pneumonia, which was caused by legionella pneumophilia, non pneumophillaspecies and mycobacterium species including mycobacterium avium, staphylococcal and streptococcal infection. [31, 29, 30]

The most serious potential threat present in aerosols is M. tuberculosis, the organism that causes TB. In the past, TB was viewed as an occupational hazard of dentistry.[36, 37] Patients known to have active TB should be treated using special respiratory precautions so that the aerosols produced during treatment can be controlled. Patients with undiagnosed, active, infectious TB, however, remain a risk for the dental team and other patients.

The saliva and nasopharyngeal secretions also may contain other pathogenic organisms. These may include common cold and influenza viruses, herpes viruses, pathogenic streptococci and staphylococci, and the SARS virus. The use of universal precautions with all patients initially was based on the assumption that all patients may have an infectious blood borne infection, such as with hepatitis B virus, hepatitis C virus and HIV. It also should be assumed that all patients may have an infectious disease that has the potential to be spread by dental aerosols; thus, universal precautions to limit aerosols also should be in place.Recent studies have highlighted the spread of infection through the air resulting from the most intensive aerosol and splatter emission that occur from an ultrasonic scalar tip and bur on a high-speed hand piece. [38, 39]Basu et al. [40] did a survey of aerosol-related symptoms in dental hygienists using ultrasonic scalars. They found that symptoms such as nasal irritation, persistent cough, runny eyes, and itchy and dry skin were more common in dental hygienists than in nurses and hospital staff.

Dental prostheses should be disinfected before they are sent to the laboratory and upon return to the dental clinic [41] but, despite rigorous control of sterilization and disinfection of instruments in dental clinics; prosthetic appliances do not receive adequate infection control. Potentially pathogenic microorganisms, such as Gram-negative bacilli of the genus Acinetobacter, as well as Micrococcus, Pseudomonas, Moraxella and Alcaligeneshave been detected contaminating pumice in commercial laboratories [42, 43]. These bacteria, which are not part of normal oral flora, can cause serious diseases if passed to patients whose dentures are polished with contaminated material and to the technician by exposure to contaminated aerosol. Williams et al. [44] reported, in 1985, the increase of cases of pneumonia in individuals exposed to lathe aerosol. Sande et al. [45] reported 10 cases of infection by Mycoplasma pneumoniae involving persons working in dental prosthetic laboratories, suspecting that these infections derived from manipulation of prostheses contaminated by these microorganisms. Therefore, the use of aprons, gloves and protective glasses by the professionals should be a routine. [46]

The dentist's face is at high-risk of infection transmission. During dental practice, central areas of the face such as inner part of the eyes and around the nose were most contaminated areas. These parts are the important areas for transmission of infection. Among occupational threats for this group, transmission of infections especially viral diseases such as Hepatitis B, Hepatitis C and acquired immune deficiency syndrome is more critical. [47] World health organization has reported 2.5% of human immunodeficiency virus (HIV) and 40% of Hepatitis B and Hepatitis C infections in healthcare staff by occupational contacts. [44]Comparing prosthetic and periodontal procedures, the latter caused more contamination in the present study. This could be because of more bleeding and soft-tissue irritation during scaling. [49] Water droplets in splash are from 50 μm to several millimeters in diameter and move 15-120 cm from a patient's oral cavity.[38, 50, 39] Splatter shows limited penetration into the respiratory system,[50] but can come into contact with the mucosa of nostrils, open mouth, eyes, and skin. They are deposited on hair, clothes and in the immediate surroundings of the splatter source.

Allergens and Irritants in Dental Clinic Through the Use of Volatile Chemical and Dust Particles Generated

The work at a dental clinic implies getting in contact with different chemical substances. The chemical substances may originate from dental materials, such as mercury from amalgam and monomers from resin based materials. The substances may be released during preparation, polishing and removal of restorations. Visual field constriction related to mercury exposure is reported.[51] Color vision examination has been shown as a sensitive indicator of subtle neurotoxic effects from exposure to solvents and heavy metals.[51]The dusts generated during routine procedures by dental technicians such as mixing powders, using silica sand for abrasive blasting,trimming and polishing of acrylic dentures and orthodontics appliances can't be avoided. Research has shown us that the dust from the types of materials that are used in dental technology contain between 54-70 per cent of respirable particles (that is, particles of less than 5 microns in size). A particular concern is the silica content of this dust, which can reach 30 per cent and may exceed maximum recommended levels during the sandblasting and grinding processes. Another is exposure to dusts from heavy metals like the cobalt-chromium-molybdenum alloys. Both exposures may lead to a lung condition known as pneumoconiosis, of which several cases have been reported as being linked to dental technology. [52] The damage can be prevented by measures such as the use of high-volume evacuation reducing spatter and aerosol formation, "no touch-technique" and proper use of personal protective equipment in the form of protective gloves and eyewear and surgical masks.

Among the risks which are fatal includes tuberculosis (TB) and severe acute respiratory syndrome (SARS). Splash of blood to the eyes, nose or mouth occurs frequently during dental procedure. The risks of transmission of HBV, HCV and HIV as a result of injury with a contaminated needle are approximately 30% (HBV when the source is e-antigen positive), 3% (HCV) and 0.3% (HIV). (Table 2) Cases reported so far, hypothesized that blood borne pathogens like HIV, HBV, and HCV can be transmitted through the inhalation of blood containing aerosol via the microlesion in the mucosa of the airways which acts as the potential access for such viruses [54].

Table 2: Risk to dental surgeon and patients through aerosol

Condition	Habitat	Routes of transmission
1. Common cold	Upper respiratory tract	Aerosol, contact
2.Sinusitis	Upper respiratory tract	Aerosol, droplet
3.Pharangitis	Upper respiratory tract	Aerosol, droplet
4.Pneumonia	Respiratory tract	Aerosol, droplet
5.Tuberculosis	Respiratory tract	Aerosol, droplet
6.SARS	Respiratory tract	Aerosol, droplet, intimate contact
7.Avian influenza(H5N1 flu)	Respiratory tract	Aerosol, droplet, intimate contact
8. Avian influenza(swine flu)	Respiratory tract	Aerosol, droplet, intimate contact

Barrier Techniques Used To Reduce the Risk of Contamination

Universal Barrier Precaution

When the patient enters the dental clinic, every attempt should be made from the dentist's end to avoid cross contamination. A thorough case history, clinical examination and all the necessary investigations should be carried out. The dental team should be vaccinated, protective equipment which include gloves, gowns; face shields, hair protection, mouth masks, and goggles/eye wear are the other preventive steps to be taken.

Immunization of Dental Personal

Immunization of dental personnel against Hepatitis A [39], Hepatitis B [39,55], Influenza, Mumps, Measles, Tetanus, Rubella, Tuberculosis, whooping cough [55], Varicella, MMR , DPT, Rubeola, Meningitis, Polio and Diptheria for infection control should be done at proper periodic intervals.

Pre Procedural Mouth Rinse

One of the study demonstrated that the microbial load in the saliva was reduced in both chlorhexidine and herbal group (p value = <0.05). It was found that chlorhexidine mouthwash could reduce the bacterial load to 99.91% in saliva while herbal mouthwash could reduce the bacterial load to only 58.27%. Hence chlorhexidine mouthwash has better antibacterial activity than herbal mouthwash. However the percentage reduction of the bacterial load in the aerosol in chlorhexidine group was much higher in comparison with the herbal group. Therefore chlorhexidine is proved to be better than herbal mouthwash. The reason to this could be due to better penetration of chlorhexidine to dental plaque. [56] Hence Pre-procedural rinses with water and 0.12 to 2% chlorhexinegluconate or essential oil containing mouthwashes for duration of 60 seconds can cause substantial reduction in bacterial counts.

Use of Rubber Dam

During many dental procedures, the use of a rubber dam will eliminate virtually all contamination arising from saliva or blood. If a rubber dam can be used, the only remaining source for airborne contamination is from the tooth that is undergoing treatment. This will be limited to airborne tooth material and any organisms contained within the tooth itself.

Use of High Volume Evacuator

The use of a high-volume evacuator, or HVE, has been shown to reduce the contamination arising from the operative site by more than 90 percent. During restorative dentistry, the HVE often will be used by an assistant who is able to guide and aim the vacuum in a manner that eliminates or greatly reduces the visible water spray produced during dental procedures. It has been shown that the number of CFUs produced during dental procedures is reduced greatly when an assistant uses an HVE.[57]

Instrument Sterlization

Patient-care items are categorized according to Spaulding classification system as critical, semi-critical, or noncritical, depending on the potential risk for infection associated with their intended use.[58, 59] The biological indicators (spore strips of Bacillus stearotheromophillus) must be checked for every sterilization cycle and if not then at least once in a week with physical and

chemicals methods of monitoring of sterilization cycles. Maintain the record of all these monitoring systems.

Disinfection

Prostheses, inter treatment materials and non-sterilizable equipment must be cleaned with soap and water and disinfected with a hospital-level disinfectant if they become contaminated. If ultrasonic cleaners are used for cleaning or the disinfecting step, care must be taken not to overheat the material or disinfectant while in the ultrasonic cleaner. Spraying or soaking these items in the disinfectant in a separate container or bag is the method of choice[60].

Laboratory Asepsis

On the polishing lathe the pumice solution should be made by suspending the pumice in tincture of green soap or other surfactant and possibly adding an effective disinfectant solution to the mix. [61]This will prevent colonization from airborne and other organisms that may find themselves in the warm wet pumice environment. The pumice should be changed daily and the machine should be cleaned and disinfected daily. Bench tops and work areas should be cleaned daily or. Surface disinfection protocols are the same in a Dental laboratory as that in a dental clinic. [61]

Conclusion

From an infectious point of view, dentistry has never been safer than it is today for both patients and dental team.The aerosols and splatter generated during dental procedures have the potential to spread infection to dental personnel and other people in the dental office. While, as with all infection control procedures, it is impossible to completely eliminate the risk posed by dental aerosols, it is possible to minimize the risk with relatively simple and inexpensive precautions with immunization protocols requires attention. CDC and ADA protocol should be followed with at most consciousness to minimize the risk among the patients and the dentists.

Abstract

Myasthenia gravis is an autoimmune disorder characterized by antibody meditated destruction of acetylcholine receptors at the neuromuscular junction. Treatment with intravenous immunoglobulin (IVIg) has been shown to have fewer side effects and should therefore be considered as a promising therapy in the treatment of myasthenia gravis. This review aims to recognize the potential of intravenous immunoglobulins in treating myasthenia gravis.

Key Words*: intravenous immunoglobulins, myasthenia gravis, autoimmune.*

Introduction

Myasthenia gravis is an autoimmune disorder of neuromuscular transmission associated with a deficiency of acetylcholine receptors. Current therapies that influence the immune response include: thymectomy, corticosteroids, non steroidal immunosuppression and plasmapheresis.Treatment of neurological disorders by means of intravenous immunoglobulin (IVIg) is an increasing feature of our practice for an expanding range of indications. For some there is evidence of benefit from randomized controlled trials, whereas for others evidence is anecdotal.The management of patients with myasthenia gravis usually involves a combination of these therapies to produce an adequate response[1-3]. Such a combination exposes the patient to asignificant level of toxicity. However, treatment with intravenous immunoglobulin (IVIg) hasshown fewer side effects and shouldtherefore be considered a promising therapy in the treatment ofmyasthenia gravis.

Myasthenia Gravis

Myasthenia gravis is adisorder of neuromuscular transmission that is antibody mediated and that leads to loss of functional acetylcholine receptors at the endplate and consequentfatiguable muscle weakness. This disease is characterized by weakness and fatigability of voluntary muscle changing over shorter or longer periods. Acute exacerbations are life-threatening because of swallowing difficulties or respiratory failure.The prevalence of myasthenia gravis among middle-aged and older patientshas increased. The disease occurs, for the most part, in the third decade, and is rare before the age of 15, or after 70. In approximately 60 percent of the patients the disease develops between the ages of 20 and 40[4]. Recent studies have shown an increased prevalence of the disease among middle-aged and older patients[5-8]. This may be a result of both an improved prognosis among elderly patients.The need for universally accepted classifications, grading systems, and methods of analysis for patients undergoing therapy for myasthenia gravis is widely recognized and is particularly needed for therapeutic research trials.

One patient, thrown to the ground by blast in the blitz, was unable to rise again, Another developed ptosis and diplopia the day after an accident at work, in which he was unharmed but was certain he was about to be killed. Two women had ptosis for the first time at their wedding, and one when she found evidence of her husband's infidelity, Very many attributed the onset to anger, quarrels, worry etc. with details too circumstantial to discount. All had myasthenia from then on, (as one woman ruefully remarked 'girls with myasthenia shouldn't fall in love'). A few women first had symptoms during

pregnancy, and four cases were detected by abnormal response to relaxant drugs used by anaesthetists.

Later relapses were attributed to the same factors, but other causes were the pre-menstrual period, cold, warmth (especially a hot bath) and allergy to shell fish (two cases) and one case followed soon after inoculation. Sunlight often caused ptosis and blurred vision, and a few patients asserted that it also caused generalized weakness.There can be quite surprising variation from day to day and even hour to hour. Physical exertion is certainly a factor, but I believe that the emotional state is' more important. This raises the question of remissions. Remissions are generally considered so characteristic of myasthenia as to cause difficulty in evaluating therapy. It is quite true that sudden improvement can occur, but complete remission lasting for more than a month is seen in less than half of the patients, and more than one long remission is very rare. Furthermore, most of the 'worthwhile' re- missions occur during the first 3 years, though there are notable exceptions to this rule. This is the period which sees most of the deaths from myasthenia (especially the first year of the disease) and thymectomy, to be beneficial, is best done during the first 5 years.

The impressionthat the 'active' stage of the disease is limited to this period and the subsequent course depends on the extent of the damage occurring then. This is not to say that the patient is out of all danger if he survives for 5 years. On the contrary, the 'brittleness' of the remissions and the delicate balancetakes place is significant. Sudden death may occur 'from apparently trivial respiratory obstruction, and many examples could be quoted. Nevertheless these catastrophes are due to the pre-cariousness of an adaptation which is sufficient for normal existence without permitting mobilization of reserve muscular power in emergency. They are notusually due to sudden relapses or to a progressive disease process, though second waves of renewed activity do occur sometimes, particularly after upper respiratory infection or renewed emotional stress.

Pain is quite common in weak muscles, usually an ache which is presumably due to the extra effort required to maintain posture. This often causes headache, pain round the eyes, backache etc. Sometimes the muscles are actually tender, and pain has been noted to persist even while resting in bed. One isirresistibly reminded of polymyositis. A few patients have complained of mid-sternal pain, often on stooping, which is sometimes associated with palpitations. Other sensory symptoms are rare but cannot be ignored as they have been present in other series. Most often there is tingling of the hands, thighs, or face, sometimes unilaterally. It can be considered that there was a mechanical explanation, as from shoulder- girdle drop, or a misinterpretation by

the patient of muscle 'stiffness'. Deafness, often variable, sometimes occurs, from Eustachian block in pharyngeal paresis or an unusual deafness for low frequencies which may be caused by paralysis of the tensor tympani. If the stapedius muscle is weak the patient has hyperacusis. Some authors describe objective sensory changes including a few cases of loss of taste or altered olfactory sensation which are difficult to explain. Epilepsy was present in two of my cases and unexplained blackouts in another three, These were thought to be coincidental, but Hoefer et al. (1958) found an unusually high incidence of epilepsy associated with myasthenia [9]. Raised protein in the cerebrospinal fluid was present in nine cases, but the fluid was only rarely examined. There is a substantial collection of similar cases in the literature.

Intravenous Immunoglobulins

Intravenous immunoglobulins (IVIg) were developed 20 years ago for the prophylaxis support of immunodeficient patients. However, IVIg have been increasingly used since 10 years, in the treatment of many autoimmune and inflammatory diseases raising the possibility of product shortages and ever increasing costs in the near future. Surprisingly, the immunomodulatory mechanisms of action of IVIg are unclear because of the diversity and often contradictory Fc, F(ab′)2, and non-IgG-related mechanisms that have been proposed from clinical observations and from results obtained in various in vitro and in vivo experimental model. For a increased and rationalized clinical use of intravenous immunoglobulins and for developing substitutes for some of the immunomodulatory indications in order to ensure immunodeficiency patients of long-term availability of plasma-derived IVIg, the briefing of mechanisms of action of IVIg is crucial.

Intravenous immunoglobulin (IVIG) is a therapeutic compound prepared from pools of plasma obtained from several thousand healthy blood donors. Intravenous immunoglobulin has been used in the treatment of a wide range of primary and secondary immunodeficiencies for more than 20 years. Experimental evidence retrieved in the previous years are suggestive of the fact that the therapeutic beneficial effect of IVIG in immunodeficiencies reflects an active role for IVIG, rather than a mere passive transfer of antibodies.

The large donor pool ensures the diversity of antibody repertoires that include antibody specificities to a wide spectrum of antigens. IVIG contains a sampling from the complete array of variable regions of antibodies similar to those present in normal human serum [10].

Antibodies that occur in the absence of pathological conditions or deliberate immunizations are referred to as natural antibodies (NAb), and IVIG represents a privileged source of natural antibodies. NAb have been attributed with a variety of functions, including first- line defence against pathogens [11-13].. The presence of antibodies to recurrently occurring pathogens may thus be critical for the replacement therapy of patients with humoral immune deficiencies.

IVIG has been used in agammaglobulinaemia therapy for the past 20 years [10,14]. IVIG is significantly seen as a recommended treatment for most primary immunodeficiencies (PID) [15]. IVIG is used in patients with X- linked agammaglobulinaemia (XLA), common variable immunodeficiency, X- linked hyper- immunoglobulin (Ig)M, severe combined immunodeficiency, Wiskott–Aldrich syndrome and selective IgG class deficiency. In addition, IVIG is used extensively in the treatment of an increasing number of autoimmune and inflammatory disorders.

Intravenous Immunoglobulins in Myasthenia Gravis

The extensive range of effects associated with IVIg treatment reflects the functions of circulating immunoglobulins in the maintenance of tolerance to self and immune homeostasis in healthy individuals. The mode of action of IVIg is complex, but efficacy depends on two general types of mechanism: antigen binding and modification of various effector functions. Antigen binding is mediated by the Fab part. The effector functions include binding to the various Fc receptors resulting in modulation of expression and function of Fc receptors, complement activation, complement binding, anti-inflammatory effects resulting from interference with the cytokine network, provision of anti-idiotypic antibodies, and modulation of T and B-cell activation. [16-25] It should be emphasized that these mechanisms overlap, and the outcome of IVIg treatment manifests as a combination of many different effects.

IVIg has been studied in a number of trials over the past ten years. Intravenous immunoglobulin treatment for myasthenia gravis was first done inthe 1980s [14,15]. Several such short earlyseries were reviewed in 1994 [26]. 78% of patientsimproved overall, but most received additional immunological therapy, which may account for theexceptionally long duration of improvement (30 days to 2 years). An open retrospective study ofIVIg (2.0 g/kg body weight) in 14 patients with generalized MG, many of whom also receivedadditional immunological therapy, reported significant improvement that began within a few daysof treatment initiation and peaked at 2

weeks[27]. Whereas severe cases usually responded,thosewith mild disease did not (level IV evidence).

In 10 patients with severe generalized MG reportedimprovement in all in an open prospective study of 5 days IVIg followed by single treatments every 6 weeks [28]: each patient was receiving additional immunological therapies, but itproved possible to reduce these over the year long study (level IV evidence. A retrospectivestudy of the reports of IVIg therapy in 10 patients with juvenile MG (age range 2–18) reported improvementin eight [29] and treatment was well tolerated. A consensus meeting on IVIg [30]came to a conclusion that IVIg therapy was very helpful in acute deterioratingdisease, minimizing the risk of bulbar or respiratoryweakness requiring intensive care support. A role inchronic state of the disease was not established however, and its use as a primarytreatment in MG was not recommended (level IV evidence).Aseptic meningitis has recently been reported as a complication of IVIg therapy in the treatment of myasthenia gravis [31].

Conclusion

A review of recent studies enables us to put forwardsome positive and negative aspects of IVIgtreatment in MG. The negative aspectsinclude: the temporary nature of theresponse, the high cost of the product, andthe injection of human blood and the accompanyingrisk of infection. However, the positiveimpact of IVIg therapy on MG areevident in the high rate of response, rapidonset of improvement, the lack of recognized short- and long-term toxicity, the reproducibilityof the response (the temporarynature of response may be overcome by usingrepetitive courses) resulting in the reductionof corticosteroid therapy in the majority ofpatients. Myasthenia gravis can cause facial paralysis [32][33].

Abstract

The frequency of malocclusion in adults is equal to or greater than observed in children and adolescents. Align Technology Inc addressed the demand for an esthetic alternative to braces by developing an ‘‘invisible’’ method of orthodontic treatment (Invisalign) that uses a series of computer-generated, clear, removable aligners to move the dentition. Esthetic concerns during orthodontic treatment may be a significant factor, with many patients not wanting to show metal or partially clear fixed appliances with arch wires when they smile.The aim of this review is to provide comprehensive information about invisible braces in dental practice.

Key Words: Ceramic brackets, Invisalign, Essix appliance, Lingual braces, Clear aligners

Introduction

The face is said to be the most important physical characteristic in the development of self-image and self-esteem, as positive social interactions have been shown to result in better interpersonal relationships and more self-confidence. Any significant deviations from the norm may result in feelings of insecurity related to appearance, inhibition in social contacts, and comparison of self with others considered to be 'superior', all of which may negatively affect the quality of life of the individual [1].

Orthodontic treatment mainly involves the correction of facial asymmetry, malocclusion, thus improving the appearance and function of the patient. There are basically two different types of appliances, removable and fixed. Both these appliances help in the movement of teeth, retraining of muscles as well altering the growth of the jaws. These appliances apply pressure over the muscle for producing the desired effects. The treatment likely to be given for each and every patient is purely based on the severity of the malocclusion. The treatment mostly involves the metal brackets and wires, which may make some patient to neglect the treatment. Thetooth coloured brackets and wires were gradually upgraded. But this did not account for the amount of force that was given by the metal brackets and wires. The cost and the bulk of tooth coloured brackets combined with the wires were expensive when compared to the metal. The clear plastic aligners, also known as the clear aligners then came into picture. They are tough to straighten the teeth. They are made from clear plastic, so they are nearly invisible. The lingual orthodontics has also gained importance in the last few years. But the technical complexity in the placement of brackets in the lingual and palatal region and its cost remain to be the same and has restricted its use.Although Orthodontic treatment has many recognized benefits, including improvement in dental health, function, appearance, and self-esteem, nevertheless orthodontic appliances can cause unwanted complications if adequate care is not taken during the treatment. It is important that the patients are aware of these potential risks, so that they can know their responsibilities and the expectations placed on them during the treatment [2].

In orthodontics the long term stability of the achieved result remains to be a fundamental issue of concern and debate. Orthodontic retainers are exclusively made appliances, which are usually made of wires or clear acrylic, that hold the tooth in its stable position after orthodontics treatment, orthognathic surgery or any method of realigning teeth. They are most often used after orthodontic correction to keep the teeth in position while allowing remodelling of the surrounding tissues and other structures and to hold the teeth in an ideal

aesthetic and functional relation and to prevent the inherent tendency of the teeth to return to their former position (relapse) [3].

One of the major challenges that are usually faced in orthodontics is to achieve an excellent result with appliances that are both aesthetic as well as comfortable. There are currently enormous interests in so-called 'invisible orthodontics'. This has been contributed to by the intensive marketing campaigns run by the manufacturers themselves for various removable clear aligner systems. However, the availableresearch tells us that the mean accuracy of tooth movement with Invisalign is only41%. Aligner systems, because of their inherent biomechanical limitations, can only accomplish certain types of tooth movement. Their role is therefore limited to the correction of specific malocclusions [4]. In this review, invisible braces in orthodontic treatment have been elaborated.

Invisible Orthodontics

History

The possibility of using clear overlay orthodontic appliances was introduced in 1946, when Keslingdevised the concept of using a series of thermoplastic tooth positioners to progressively move misaligned teeth to improved positions. In 1997, Align TechnologyG (Santa Clara, Calif) adapted and incorporated modern technologies to introduce the clear aligner treatment (CAT). Although CAT has been cited as a safe, esthetic, and comfortable orthodontic procedure for adult patients, only a few investigations[5, 6] have focused on the predictability of orthodontic tooth movement. In 2005 Lagrave`re and Flores-Mir6 published a review in which only two studies met their inclusion criteria related to Invisalign therapy efficacy. In 1971, Ponitz [7] introduced a similar appliance called the "invisible retainer" made on a master model that prepositioned teeth with base-plate wax. He claimed that this appliance could produce limited tooth movement. Sheridan and others [8] later developed atechnique involving interproximal tooth reduction and progressive alignment using clear Essix appliances.

Types of Invisible Braces

Ceramic Brackets

After their introduction in 1986, various types of ceramic brackets are currently available by all major orthodontic manufacturers, thus gaining widespread popularity and becoming an integral part of the clinician. All currently available ceramic brackets are composed of aluminum oxide. However, because of their distinct differences during fabrication, there are

two types of ceramic brackets, namely, the polycrystalline alumina and the single crystal alumina. The manufacturing process plays a very important role in the clinical performance of the ceramic brackets. Because production of polycrystalline brackets is less complicated, these brackets are more readily available at present. The most apparent difference between polycrystalline and single crystal brackets is in their optical clarity. Single crystal brackets are noticeably clearer than polycrystalline brackets, which tend to be translucent. Fortunately, both single crystal and polycrystalline brackets resist staining and discoloration. Ceramic brackets come in a variety of edgewise structures including true Siamese, semi-Siamese, solid, and Lewis/Lang designs. Many brackets are made by specialized ceramic manufacturers and are sold under proprietary names by manufacturers or distributors of orthodontic products [9].

Ceramic brackets appeared in the mid-1980s and were better able meet patients' functional and esthetic demands; plastic brackets had left much to be desired, particularly regarding color stability, deformation, torque, friction, tie-wing fracture, and debonding.With improvement in the physical and mechanical properties of esthetic brackets by the incorporation of ceramic or glass particles and a metal channel as reinforcement in plastic brackets,in addition to surface preparation of the channel in the ceramic brackets, the demand for esthetics became the main target. Less visual perception, to which the term esthetic is related, was desired. Various ceramic brackets are monocrystalline brackets, Polycrystalline brackets and zichronia brackets. The major advantages of ceramic brackets are esthetics, tooth colored material and acceptance by patient.But there are certain disadvantages of ceramic brackets. Ceramic brackets have a higher incidence of fracture during debonding, particularly with the conventional debonding techniques. Ceramic brackets are unable to withstand strong torsional forces, especially after the bracket surface has been nicked during treatment. Enamel wear occurs if ceramic brackets contact opposing tooth surfaces. Therefore, placement of ceramic brackets is contraindicated on the lower anterior teeth in cases with deep overbite and minimal overjet. In such cases, sufficient overjet has to be created before bonding the lower incisors. Similarly, during maxillary incisor retraction, the overbite should be reduced first so that the maxillary incisors do not contact the mandibular ceramic brackets. Ceramic brackets can cause nicks in the arch wires, resulting in more friction between the bracket and the arch wire. This can decrease the efficiency of tooth movement. The use of ceramic brackets in patients who will undergo orthognathic surgery should be discouraged. The fracture of the brackets before, during, or after surgery creates the potential for undesirable and avoidable cornplications [10].

Self-ligating ceramic brackets have become very popular over the course of the last decade. Effective ligation is important, as it ensures that forces generated between the archwire and the brackets are transmitted to the tooth. In later stages of treatment, when single teeth or groups of teeth are slid along the archwire by traction from elastics or coil springs, the ligation maintains the existing alignment. As a consequence, the control of the archwire in the slot is always coupled with resistance to sliding (RS) arising in the mechanical system [11].

Invisalign

Joffe [12] suggested that the Invisalign appliance is most successful for treating mildlymalaligned malocclusions (1 to 5 mm of crowding or spacing), deep overbite problems (e.g.,Class II division 2 malocclusions) when theoverbite can be reduced by intrusion oradvancement of incisors, nonskeletally constricted arches that can be expanded with limitedtipping of the teeth and mild relapse after fixed-appliance therapy. Use of the Invisalignappliance is relatively new fororthodontists and is still being developed. Currently, fewclinical studies and case reports have assessed the effectiveness of this technique. AlthoughAlign Technology has suggested guidelines for its appropriate use,clinicians haveencountered numerous limitations when using the appliance.

Method of Fabrication

The Invisalign appliance involves a series of aligners made from a transparent, thin (typically less than 1 mm) plastic material formed with CAD-CAM laboratory techniques. Thesealigners are similar to the splints that cover the clinical crowns and the marginal gingiva.Each aligner is designed to move the teeth a maximum of about 0.25 to 0.3 mm over a 2-week period, and is worn in a specific sequence. The Invisalign appliance is currently recommended for adults and for adolescents with fullyerupted permanent teeth who meet an acceptable standard of compliance.

Advantages of Invisalign orthodontics are:1) It is removable when compared to metal braces, 2)Convenient as there is no worry of breakage of wires or brackets, 3)Highly aesthetic and 4)As they are made of plastic, they are highly durable.

It has few disadvantages too. Temporary sensitivity of teeth and gingival and the Invisalign appliances, because of their removability, have very limited control over precise tooth movements.

Lingual Braces

With invent of lingual appliances an entirely new treatment biomechanics emerged. Orthodontists are also determined towards this goal and have given a new dimension by changing from the labial to the lingual so as to give rise to a new concept the Invisible Braces concept or Lingual Orthodontics[13-14]. Due to increasing social awareness and esthetic demands of young patients, the application of lingual orthodontics today is not only restricted to adults, but has been extended to adolescents as well.

This kind of braces is used in cases where stability is questionable and long term retention is planned. Has four main indications such as, maintaining lower incisor position, diastema maintainence, implant or Pontic space maintainence, retaining closed extraction spaces.

Types of lingual braces: Banded canine to canine retainers,bonded lingual retainers,Band and spur retainers.

Self ligation in lingual orthodontics was first described by Macchiet in 2002 the Philippe Self Ligating Lingual Brackets that can be bonded directly to the lingual tooth surfaces. Self ligation in lingual orthodontics has come with interactive lingual brackets. It has a non-locking rotating clip resulting in unique flexibility. It comes with a self-ligating clip flexes like an elastomeric ligature and therefore responds to the actual malocclusion without losing force, which reduces binding and prevents notching especially with highly rotated teeth. The Evolution SLT Smart cap is a unique indirect bonding system based on the principles of the HIRO system. It offers the practitioner the benefits of bonding each tooth individually, offering at the same time the speed of a full bonding tray.

Another precise Lingual Self ligating system comes as Inovation L by GAC which is an interactive, twin, self-ligating lingual bracket system. Only an interactive bracket provides full functionality throughout the course of treatment. Passive function is achieved with a round Sentalloy NiTi wire that slides freely for efficient leveling and alignment. This is created with the light seating of a BioForce wire into the base of the slot so programming may be expressed and rotations are corrected. Active function with full control is provided by the introduction of a full-size Resolve Beta-Ti wire, enabling full expression of the bracket’s torque and achievement of the desired result. Dentaurum has come up with the World‘s first Nickel free Lingual Brackets called Magic. Due to the magic bracket's unique geometrical form, arch wires can be inserted occlusally. The innovative combination of occlusal and horizontal slot directions enables the arch wire to be automatically pressed into the slot.

The Incognito Lingual Appliance

Lingual orthodontics has advanced to a highly sophisticated level where CAD/CAM (computer-aided design/computer-aidedmanufacture) technology is employed to manufacture both thebrackets and arch wires for each patient individually in the incognitoappliance system. The incognito lingual appliance system is used to treat both teenagers and adults. It can be used in combination with functional appliances like the Herbst appliance, and 'bite jumpers' like the Forsus appliance. It can be used without difficulty in the management of orthodontic patients who require orthognathicsurgery.

Technological developments mean that lingual orthodontics is now far more acceptable to the patient, as discomfort and interference with speech and mastication have been minimised. Although lingual orthodontics is more difficult than labial orthodontics to perform, it can achieve a high standard of orthodontic result comparable to labial orthodontics when properly applied. It is, like labial orthodontics, dependent on patient compliance.

2D Lingual Brackets

2D Lingual Brackets are bonded to the inside of the dental arch. They are invisible from the front and give you that carefree smile from the beginning. 2D Lingual Brackets offer the most important advantage of braces: they work around the clock and you do not need to motivate yourself to wear them regularly. 2D Lingual also acts close to the so-called resistance centre of the teeth and moves them effectively and quickly. 2D Lingual Brackets are the attest brackets on the market at a height of only 1.3 to 1.65 mm, depending on the design. Due to the integrated clips, no further retaining elastics are required, which would only add volume and impair wearing comfort. The optimally rounded edges ensure that the brackets are not uncomfortable or irritating. Very soon after placement you will be able to speak with- out a noticeable difference and eat as usual.

A three-dimensional (3D) surface scanning system was recently introduced in dental fields and has been used most extensively for example, for assessing morphological changes in maxillofacial surgery or in orthopedic treatment with a functional appliance. Another use for the 3D data acquisition in orthodontics is bending art system (BAS) or Invisalignsystem introduced as a new treatment modality [15].However, research on the various clinical

applications of 3D digital model is still in its early stage, as it has been used as a simple model analysis, a digitized data storage. It can be divided into 7 parts:

1. The measuring accuracy and process of the 3D model scanning technique was evaluated in terms of linear, surface and volumetric parameters. The diverse clinical applications of model analysis, including measuring basal arch width, or sectional areas concerned will be presented.
2. Giving the evidences that the superimposition of the 3D digital maxillary model is clinically as reliable as cephalometric superimposition for assessing orthodontic tooth movements.
3. Presenting the clinical cases, using the superimposition technique for the 3D measuring of orthodontic tooth movement in maxilla.
4. Describing the clinical procedure for digital diagnostic setup.
5. Introducing a novel method concerning the volumetric assessment of tooth wear using 3D reverse engineering technology.
6. Presenting a quantitative 3D soft tissue facial analysis using a color coding system.
7. Presenting feasible methods of the integrating 3D digital model into a 3D facial image to visualize the anatomic position of the dentition [16].

The main advantage is that, the facial surfaces of the teeth are not damaged, facial gingival tissues are not adversely affected, he position of the teeth can be more precisely seen, facial contours are truly visualized since the contour and drape of the lips are not distorted by protruding labial appliances, most adult and many young patients would prefer "invisible" lingual appliances if costs, treatment times, and results were comparable to those of labial appliance treatment.

But there are certain cons for the same. They are, increased chair time, banded variation may interfere with oral hygiene maintainence, more cumbersome to insert, more prone to breakages and finally loss of healthy tooth material.

Clear Aligners

Orthodontic treatment is mainly surrounded with metals like wires and brackets. This esthetic compromise repels adult orthodontic patient from accepting treatment. Tooth colored brackets and wires tried to overcome these limitations but could not proved to be good option to metals because of its bulk, and cost. In last few decades lingual orthodontics has gained

worldwide popularity in terms of esthetics but its widespread use is restricted because of complexity in bracket positioning, treatment mechanics, limited access to the lingual / palatal surface and cost. In addition, bracket bonding procedure endangers the precious enamel to chemical insult, making it unaesthetic and susceptible to microbial attack. So, clear aligners have emerged as a promising option for adult orthodontic patients.

Clear Aligner Therapy is an orthodontic treatment modality in which the patient wears a series of customized clear, removable aligners that gradually moves the teeth to a desired position. The total number of aligners varies depending on severity of malocclusion. Clear aligners do have some limitations and inconveniences. The benefits of Clear Aligner Therapy generally outweigh the drawbacks. Clear aligner treatment falls into two basic categories. The first category consists of those thermoformed appliances, sometimes known as Essix Retainers that are fabricated by making adjustments to the tooth positions on plaster or stone models and fabricating one or more aligners to correct a minor malocclusion. These types of appliances are sometimes fabricated in the orthodontist's office or sometimes sent out to commercial laboratories. These types of in-office prepared aligner systems have been in use since around 1994. Invisalign is a proprietary orthodontic technique that uses a series of computer generated custom plastic aligners to gradually guide the teeth into proper alignment [17-19].

In one study, metallic brackets in use for one month were found to be colonized by cariogenic microorganisms and periodontal pathogens [20]. In another study, a negative effect on microbial flora was observed with long-term utilization of orthodontic appliances. The study recommended patients be put on short recare intervals during therapy [21]. During treatment, there are strategies that can be used to minimize caries and its precursor, demineralization. When used to bond brackets, resin-modified glass ionomer cement and fluoride-releasing resin composite have been successfully usedto inhibit demineralization [22].After retreatment of anterior crowding and open-bite relapse with the Invisalign appliance, Womack and others [23] found that the position of the maxillary central incisors was superior to that of the canines and posterior teeth. Djeu and others found that fixed appliances were superior to the Invisalign appliance for treating buccolingual crown inclinations, occlusal contacts, occlusal relationships, and overjet. In their 1998 study comparing Essix and Hawley retainers, Lindaurer and Shoff found that one sixth of their patients lost their appliances; the majority of these losses were ascribable to the appliances being clear and removable. Aligners from the Invisalign appliance have very similar properties to those of Essix appliances [24].

Conclusion

Recently the success of a complete orthodontic treatment is based on achieving facial balance, and a balance between functionality, aesthetically treatment and patient's aspirations. The aesthetic aspirations are now found in both male and female, most commonly in the younger population of patients. In the aesthetic aspect, the invisible orthodontics is playing a crucial rolein also the functionality aspect. Without compromising the efficiency of the appliance and also having a better aesthetic harmony for the patient invisible orthodontics is found to be one of the best treatment options. Thorough efforts, methodological approach, and vast experience gained over the years has proved that this specialty of orthodontics has the answer to the ever increasing cosmetic demands of the patients who insist on appliances which are not seen to the outside world and at the same time want to get their malocclusion treated. Today, the main goal is to achieve facial balance, and the development of orthodontic treatment is the balance between esthetical treatment, functionality and a patient's aspirations. Esthetic aspirations are now universal and involve younger patients including both male and female adolescents. In this regard, invisible orthodontics, which is highly esthetic play a fundamental part in achieving dental alignment. A smile revealing esthetic harmony is very important at any age as difficult as that of adolescence. Invisible orthodontics thus represents the best solution for meeting the needs of the patients without the risk of damaging functional efficiency.

Abstract

Liposomesaresphereshaped vesicles, consists of oneor morephospholipid bilayers. Theyarenon-toxic, flexible, biocompatible, biodegradable and non-immunogenic. Theyfunction in drugtargetingcarryboth hydrophobic and hydrophilic molecules. Liposomes deliver drugs bydiffusion rather than bydirect cellfusion.Liposome has the natural abilityto target cancercells. Theyare also used in textile industries.

Key Words:*Drug deliverysystemusingliposomes, surfactant,encapsulation, lipid spherules.*

Introduction

Liposomes was initially explained by the British hematologistDrAlec D Bangham FRSin the year 1961 and was published in the year1964,at theBabrahamInstitute,which is situated in Cambridge.Liposomesare colloidal and vesicularstructures that are madeof oneor morelipid bilayers with acentral coreof equal numbers of aqueous solution. Theword liposomeis obtained from twogreekwords namely the “Lipos” which means fat and “Soma” which means body. These liposomes are concentricbleeder vesicles inside which an aqueous volumeis totallyenclosed bya membraneous lipid bilayer. Membranes areusuallymadeof phospholipids, which are molecules that haveahydrophilic headgroupandahydrophobic tailgroup. Thehead of the liposome is attracted to water, and thetail of the same , which is madeofalonghydrocarbonchain,is repelled by water[1]. While the phospholipids aredispersed in water, they instantlyform closed structurewith internalaqueous environment surrounded by thephospholipidbilayermembranes, this kind of vesicular system is calledas liposome[2]. The phospholipid bilayer is formed when the hydrophobic tail of both layer faces each other. Liposomes arebiocompatible, biodegradable and target drugto organsystems.

Liposomes technologyis used in various fields, like the pharmaceuticals,cosmetics, foods, detergents, textiles, and many other applications, because of their abilitytoliberate and

encapsulate slowly[3,4].Liposomes are basicallymadeofnaturallyderivedphospholipids that aremixed with lipid chainslike the eggphosphatidylethanolamineor they are made ofpuresurfactant components namely the DOPE which is the dioleoylphosphatidylethanolamine. Liposomes generallythough notby definition, it is found to be made up of a coreof aqueous solution ; and lipid spheres which contain noaqueous materials called micelles, anyways , reverse micelles could be made to encompass an aqueous environment also[5].

Based upon the composition and the molecular structure , liposomes can separate hydrophobic or hydrophilic molecules from the solution[6,7]. These vesicles are not considered to be strong formations but rather they are fluid entities which are complex supramolecular assemblies. Because of the dynamic properties they possessand therelatively easy manipulating ability, these liposomes have been used in a wide range in the analytical sciences as well as for drug and gene delivery.

Mechanism of Liposome Formation

Since the liposomes are made up of phospholipids, they are usually amphipathic in nature and they tend to have the ability to bind both with aqueous and polar moiety. They also have a polar head and a non polar tail.

The polar end is mainly made up of phosphoric acid and it will get bound to water soluble molecules.In aqueous medium the molecules are found in self- assembled structure and it is oriented in such a way that the pole side of the molecule tend to remain in contact with in polar environment and also at same time shieldsthe non polar part. Liposomes are being formed when these thin films are getting hydrated and stacks of liquid crystalline players tend to become fluid and gets swollen.

Once these vesicles are formed, there is a change in vesicle shape and also morphology required energy input in the form of sonic energy to obtain SUVs and mechanical energy to obtain LUVs.

Yet, in aqueous mixtures these molecules are able to get converted to various phases, and some of them are constantly stable and other tend to remain in metastable form.

Types ofLiposomes

There are various types of liposomes identified.

Liposomes areclassifiedon the basisof

-Structural parameters

-Method ofpreparation

-Composition and applications

Structural Classification

There are three types of liposomes based on structural classification . They are:

a. Unilamellar vesicles –Unilamellar is further classified into three based on the size of e vesicles as Large unilamellar vesicles orLUVs, whose size varies between 100nm-1000nm , small unilamellar vesicles or SUVs whose size varies between 20nm-40nm, and the medium unilamellar vesicles whose size varies from 40nm-80nm
b. Oligolamellar vesicles- These kinds of liposomes are made by 2-10 bilayers of lipids which surrounds an internal volume[8].
c. Multilamellar vesicles- These kind of vesicles have multiple bilayers within which they can organize their aqueous volume . This kind of organization of aqueous volume can be done in several ways. These vesicles differ from each other in the method of preparation. They are arranged in concentric circles resembling an onion where in there is a layer of large unilamellar vesicle alternating medium unilamellar vesicles and both surrounding the core of small unilamellar vesicles. With the exceptionofmultilamellar vesicles,theseothermorphologies aredifficultto obtain withouthighlycontrolled processesforformation. Giant vesicles also deservespecial attention because their sizes arelarge, rangingfrom 1 µm to morethan 100 µm[9]. These largevesicles arestudied and wellcharacterized, partiallyduethe easeofobservation via optical microscopy.

Methods ofLiposome FormationandDrug Loading

There aremanyways ofpreparinglipososmes which arelisted below. Some oftheimportant methods havebeenexplained with their steps.

Hydration oflipids in presenceof solvent , Ultrasonication, French Pressure cell, Solvent injection method , Detergentremoval , Reversephase evaporation technique, High pressureextrusion , Miscellaneous methods , Drylipid film , Emulsions , Micelle-formingdetergents, Alcohol injection technology[10].

Solvent Injection Method

In this method lipids are initially dissolved in an organic solution and then they are mixed with aqueous phase containing materials to be entrapped with liposome.

- Ethanol injection method- This was first described in the year 1972. Ethanol injection method relevance remains in the observation that a smaller distribution of small unilamellar liposomes (under 100 nm) can be attained by easily injecting an ethanolic lipid solution in water, in single step, without extrusion or sonication
- Ether injection method - The ether injection method varies from the ethanol injection method as the ether is immiscible along with the aqueous phase, which is also heated so that the solvent getsseparated from the liposomal product. The method involves the

injection of ether-lipid solutions into the hot aqueous phases above the boiling point of the ether. The ether vaporizes when it comes in contact withthe aqueous phase, and the dispersed lipid forms primarily unilamellar liposomes[11].

Detergent Removal Method

Detergent can be removed by either

- Dialysis- Liposomes, that are in the size range of 40–180 nm, arecreated when lipids are solubilised with detergent, yielding defined mixed micelles[12]. When the detergent is consequently removed by controlled dialysis, phospholipids tends to form homogeneous unilamellar vesicles with usefully large encapsulated volume.
- Column chromatography
- Bio-beads

Miscellaneous Methods

- Slow-swelling in non-electrolyte solution
- Removal of chaotropic ion
- Freeze-thawing- Freeze thawing method is totally based upon freezing of small unilamellar vesicles dispersion (SUV). And then thawing by keeping at room temperature for about 15min. Atlast subjecting it to a brief Sonication cycle that considerably causes reduction in the permeability of the Liposomes membrane. In order to make giant vesicles of diameter ranging between 10 to 50um, the freeze thaw method is being modified to involve a dialysis step against hypoosmolar buffer in the place of sonication. The method is simple, rapid and mild for entrapped solutes, and results in a high proportion of large unilamellar vesicle formation which are useful for study of membrane transport phenomenon.

Other than these there are few other methods used for the preparation of particular types of liposomes namely

- Reverse phase evaporation method- used in the preparation of single or oligolamellar vesicles
- Reverse phase evaporation method- used in the preparation of Multilamellar vesicle
- Stable plurilamellar vesicles
- Frozen and thawed medium lamellar vesicles
- Vesicles prepared by extrusion technique
- Dehydration - rehydration method.

Reverse phase evaporation method- A lipidic film is being prepared by evaporating the organic solvent with the help of reduced pressure. The system is mixed with nitrogen and the lipids are finelyre-dissolved in a second organic phase that is generallymade by diethyl ether and/or isopropyl ether. Large unilamellar and oligolamellar vesicles are prepared when an aqueous buffer

is being introduced into this already prepared mixture. The organic solvent is consequently removed and the system is constantly maintained under continuous flow of nitrogen. These vesicles are found to have aqueous volume to lipid ratios which are 30 times greater than the sonicated preparations and 4 times greater than the multilamellar vesicles. An important thing ,is that a substantial fraction of that aqueous phase which is up to 62% at low salt concentrations is being entrapped inside the vesicles, encapsulating even when large macromolecular assemblies with high efficiency[13].

Super critical reverse evaporation method:The super critical reverse evaporation method is a single-step newly developed method which has been used for liposomes preparation with the help ofsupercritical carbon dioxide. This super critical reverse evaporation method allows the aqueous dispersions of liposomes that areto be obtained through emulsion homogeneous mixture of supercritical carbon dioxide/L-R-dipalmitoylphosphatidylcholine/ethanol under adequate stirring and subsequent pressure reduction . Transmission electron microscopy results revealed that vesicles are found to be large unilamellar vesicleswith thediameters of 0.1– 1.2 microm. The trapping efficiency of these liposomes were indicated to be more than 5 times higher values for the water-soluble solute when compared to multilamellar vesicles which are prepared by the Bangham method. The trapping efficiency for an oil-soluble substance,like the cholesterol, was found to be about 63%. And the final results showed that the super critical reverse evaporation method is an excellent method that allows one-step preparation of large unilamellar liposomes which exhibits a high trapping efficiency for both the water-soluble and oil-soluble compounds.

Composition and Applications

Liposomes can alsobeclassified in terms of composition and mechanisms of intracellular deliveryinto sixtypes:

1. Conventional liposomes- Neutral or negatively charged phospholipids and cholesterol.
2. pH-sensitive liposomes- Phospholipids namely PE or DOPE with either OA or CHEMS
3. cationic liposomes- Along with DOPE
4. Immuno-liposomes- LCL or CL with attached monoclonal antibody or recognition sequence.
5. long-circulatingliposomes- Polyethylene glycol is attached to the surface membrane to prevent them from being identified by the phagocyte system. These attachments to liposomes increases the liposome circulating time in the body by decreasing the clearance from the blood stream.
6. Fusogenic liposomes- reconstituted Sendai virus envelope.

Advantages

1. Provides selectivepassive targetingto tumor tissues (Liposomal doxorubicin).
2.Increased efficacyandtherapeuticindex[9]
3. Biodegradable, biocompatible, flexible
4. Non ionic
5. Can carryboth watersoluble and lipid solubledrugs
6. Drugcan bestabilized from oxidation.
7. Altered pharmacokinetics and pharmacodynamics
8. Can be administered through various route
9. Act as reservoirof drug.
10. Flexibilityto couplewith sitespecific ligandsto achieveactivetargeting[11].
11. Efficient control of release of liposomes.
12. Resembles the natural membrane structures.
13. It has shown increased targeting prospects.
14. Liposomes gives both the lipophilic environment and aqueous “milieu internee” in a single system. It Canalso protect the encapsulated drug.
15. Easy to construct.
16. Does not accumulate in the heart and thus there is no possibility for cardiotoxicity.
17. Prevention of oxidation of the drug.

Disadvantages

1. Production cost is high.
2. Leakage and fusion ofencapsulated drug/molecules.
3. Short half-life.
4. At times phospholipid tend to undergo oxidation and hydrolysis like reaction.
5. Lower solubility.
6. Fewer stables.
7. The development of Liposomes at industrial level is very difficult becauseof its physiological and physicochemical instability.
8. They are highly prone to degradation by oxidation and hydrolysis.

Characteristics

Liposomesare generallyformed bythe selfassemblyof dissolved lipid molecules, each ofwhich contains ahydrophilic headgroup and hydrophobic tails. Theselipids takeon associations whichyield entropicallyfavorable statesoflow free energy, in some cases formingbimolecularlipid leaflets .Such leaflets are characterized by hydrophobichydrocarbon tails facingeach otherand hydrophilicheadgroups facingoutward to associatewith

aqueoussolution[14]. At this point thebilayer formation is still energeticallyunfavorablebecause thehydrophobicparts ofthe moleculesarestillin contact with water, aproblem that is overcome throughcurvatureof the formingbilayer membrane upon itself to form a vesicle with closededges[15]. This free-energy-driven self assemblyis stable and has been exploited asapowerful mechanismfor engineeringliposomesspecificallytothe needsofagiven system[16].Thevesiclesizewas foundto be varied from146±0.6 nm to 198±0.6 nm.

Applications

The following are the list of areas where liposomes are being used

1. Cancer chemotherapy
2. Gene therapy
3. Liposomes as carriers for vaccines
4. Liposomes as carriers of drug in oral treatment
5. Liposomes for topical applications
6. Liposomes for pulmonary delivery
7. Against leishmaniasis
8. Lysosomal storage disease
9. Cell biological application
10. Metal storage disease
11. Role of liposomes in Ophthalmic delivery of drugs

Liposomes used inParasitic Diseases andInfections

Since conventional liposomes areingestedbyphagocyticcells in thebodyafter intravenous administration, theyareconsidered to be ideal vehiclesforthetargettingof drugmoleculesinto these macrophages. Theyincludeleishmaniasisand several fungal infections.Leishmaniasis is a parasitic infection ofmacrophages whichaffects over 100million peoplein tropical regions and is often fatal.All the Liposomesgetsaccumulated in the verysame cellpopulation which is infected and thereforeoffer an ideal drugdeliveryvehicle.

Liposomes used inAnticancer Therapy

Manydifferent liposome formulations of multipleanticancer agents weredescribed to beless toxic than the freedrug[17]. Anthracyclines aredrugs which stop thegrowth of dividingcells byintercalatinginto theDNA and thereforekill predominantlyquicklydividingcells. Thecells are presentin tumours, butalso in gastrointestinal mucosa, hair,and blood cells and thus this class of drugs ishighlytoxic.Manydifferent formulations weretried.Inmostcases the toxicitywas reduced

about 50%. This includes both, short term and chronictoxicitiesbecause liposome encapsulation reduces thedistribution ofthedrugmolecules towards those tissues. Forthe samereason, on theotherhand, theefficacywas inmanycases compromised due to the reduced bioavailabilityofthe drug, especiallyifthe tumour was not phagocytic, or located in the organs ofmononuclear phagocytic system.In fewcases, namely thesystemic lymphoma, the effect ofliposome encapsulation had shownenhancedefficacy becauseto the sustained release effect, i.e. longer presenceof therapeutic concentrations in the circulation[18]whilein several other cases thesequestration ofthe druginto tissues of mononuclear phagocyticsystem actuallyreduced its efficacy. The most used and studied is Adriamycin which is the commercial name for Doxorubicin HCl. Liposomes can be used to deliver many such drugs and thereby minimize their toxic effects on healthy cells. Targeted delivery of drugs to cancer cells can be achieved by coating the monoclonal antibodies (MAbs) which are raised against tumor-cell specific antigens. Both In vitro and in vivo studies done by Ahmad et al. of squamous-cell carcinoma in mouse models gave the evidence that antibody-coated polyethylene glycol liposomes that contains doxorubicin were found to be more effective and less toxic than the free drugs, drugs that are incorporated into antibody-free liposomes, and also antibody- coated conventional liposomes[19,20].

Liposomes in Ophthalmic Drug Delivery

Liposome were found to be examined for ophthalmic drug delivery as it provides advantages as a carrier system. It is a biodegradable and also a biocompatible nano carrier. It can help in enhancing the permeation of poorly absorbed drug molecules by getting bound to the corneal surface and also improving residence time. It encapsulates both the hydrophilic and the hydrophobic drug molecules. In addition to this, liposomes can also improve pharmacokinetic profile, and enhance therapeutic effect, and help to reduce toxicity associated with higher dose. Owing to the versatile nature of liposomes ,they have been widely examined for the treatment of both anterior and posterior segment eye disorders. Recent approaches for the anterior segment drug delivery are being focused on improving corneal adhesion and permeation by administeringdifferent bio-adhesive and penetration enhancing polymers. Yet, in the case of posterior segment disorders, improvising the intravitreal half-life and targeted drug delivery to the retina is very much necessary. At present verteporfin is being used in the clinical aspect in photodynamic therapy for the management of subfoveal choroidal neovascularization (CNV), ocular histoplasmosis, or pathological myopia very effectively. Verteporfin is a light-activated drug that is beinginjected by intravenous infusion. In photodynamic therapy, once the

drug is being injected, a low-energy laser is applied to the retina through the contact lens so that it can activate verteporfin that results in closure of the abnormal blood vessels. But, photodynamic therapy generally does not permanently shut the abnormal vessels and choroidal neovessels tend to reappear after several months.

Liposomes in MacrophageActivationandVaccination

The automatictargeting ofliposomes bymacrophages can bestopped in various other ways, which includesthe macrophage activation and in vaccination. Few natural toxins causesstrong macrophage responsewhich leads tomacrophage activation. This process can berepeated in a similar way and also improvisedwiththe useof liposomes due tosmall molecules with immunogenic properties like the haptensand cannot causeimmune response without being attached toalarger particle.

Other Applications

Liposomes areusedfordrugdeliverydueto theirunique properties. Aliposome encapsulates aparticular region on the aqueous solution inside ahydrophobicmembrane; dissolved hydrophilic solutes cannot readilypass through the lipids. Hydrophobic chemicals are identified to bedissolved into the membrane, and in a through wayliposomesare facilitated tocarryboth thehydrophobic molecules andhydrophilic molecules.

Liposomes in Drug Targetting

The approach for drugtargettingvia liposomes involves theuse of ligands(e.g., antibodies, sugar residues,apoproteinsorhormones), whicharetagged on the lipid vesicles. Theligand identifies specific receptor sites and, therefore, causesthe lipid vesicles to concentrate at such target sites. Bythis approach the otherwisepreferential distribution of liposomes into the reticulo-endeothelial system RES (liver, spleen andbonemarrow) is avertedor minimized.Liposomes have been proved that restricting the distribution of the drug to the particular target site should cause efficacy increase even at low dosage with attendant decrease of toxicity. In fact , pumping a drug through the entire body surface is not only wasteful but also, more fundamentally, it increases the undesirable side effects. Hence, the advantages of drug targeting includes reducing of drug waste, and it is also possible to deliver a drug to a tissue or cell region which is not usually accessible to the free or untargeted drug[21]. Liposomes have been widely applied in drug targeting especially in

cancer treatment. Effective chemotherapy is highly limited by the toxic side effects of the drugs.

Liposomes inDrugDelivery

Liposomes are majorly used in drug delivery becauseof their unusual but unique structural properties. A liposome is capableof encapsulating a region of aqueous solution present inside a water repelling membrane[22]. This membrane is otherwise called as hydrophobic membrane , that will not permit dissolved hydrophilic solute to easily pass through the lipids. Whereas hydrophobic chemicals on the other hand willget dissolved into the membrane thatpermits liposome to carry both the hydrophobic and the hydrophilic molecules[23]. The molecules are transferred to the sites of action while the lipid bilayer fuses with the other bilayer such as the cell membrane.There is another way of delivering drugs which is by targeting the endocytosis events. Liposomes would be made as targets for macrophages that are present inside the body. The drugs are released and meanwhile the liposomes are being phagocytosed by the macrophage present in the body. For Endocytosis to take place in other cells , it can be initiated by administrating liposomes decorated with opsonins and ligands[24].The application ofliposomes on theskin surfaceis found to beeffectivein drug deliveryinto the skin.Liposomes tends to increasethe permeabilityof skin formultiple differententrapped drugsand at thesametime diminish theside effect of thesedrugs due to this reasonslower doses are now required.

Treatment ofHumanImmunodeficiency Virus (HIV) Infections

Several antiretroviral nucleotide analogues havebeen developed forthetreatment of patients sufferingfrom the acquired immunodeficiencysyndromes (AIDS). Theseinclude antisense oligonucleotide, which is a new antiviralagent that has shown potential therapeutic application againstHIV-virus.

Applications of Liposome inBleaching

The effect of liposomes was studied in peroxide bleachingon cellulosic and its blendswith polyester and wool fabrics[25].Thetreatment of wool fabric with chlorine-liposomes suspension was alsoreported[26].Awettingagent is required in theconventional bleachingbath ofcotton fabrics, but this step can be eliminated byusingliposomes. Thepresenceofliposomes in theperoxide bleachingbath can improvethe mechanicalproperties offabricsandtheirbrightness

Liposomes in Agro-Food Industry

The capability of Liposomes to solubilize compounds by demanding solubility properties, protect compounds from potentially harmful milieu, and helps in releasing incorporated molecules in a sustained and predictable fashion that can be used also in the food processing industry. For example, lecithin and few other polar lipids are continuously extracted from nutrients, such as egg yolks or soya beans.

Conclusion

As a conclusion, liposomes have been found to have a wide range of uses ever since it was initially noted that it was capable to self-assemble into vesicles. Their capability to form a bilayer liposome made it to be an efficient carrier. Newly formed liposomes, with highly efficient lipid molecules, and fine new formulations has managed to give various possibilities for safely and effectively treating many diseases which includes cancers.Liposomes areusedfordrug targeting,cancer therapies , in textile industryand in manyother fields.Further research is required to explorethe vast functions of liposomesand to get adeeper knowledgeabout thesignificanceof this wonder molecule.

Abstract

Liver fibrosis is defined as the excessive accumulation of extracellular matrix proteins including collagen. It represents a major worldwide health care burden (1). It represents a significant health problem worldwide of which no acceptable therapy exists (2) and not just that liver fibrosis is a major cause of morbidity and mortality worldwide due to chronic viral hepatitis and more recently from fatty liver disease associated with obesity (3). Progressive liver fibrosis is the main cause of organ failure in chronic liver diseases of any etiology. The primary source of the extracellular matrix that is responsible for fibrosis is the myofibroblast. Hepatic myofibroblasts are not present in the normal liver but transdifferentiate from heterogeneous cell populations in response to a variety of fibrogenic stimuli. It is usually considered that hepatic stellate cells and portal fibroblasts have fibrogenic potential and are the major origin of hepatic myofibroblasts. But there are at least three potential sources of myofibroblasts in the liver:

1. Resident mesenchymal cells (consisting of the quiescent hepatic stellate cell and portal fibroblasts).
2. Hepatocytes, cholangiocytes and endothelial cells.
3. The bone-marrow derived cells.

Advanced liver fibrosis usually results in liver cirrhosis, liver failure and portal hypertension and often requires liver transplantation. It is considered that the hepatic cells and portal fibroblasts have fibrogenic potential which serves as a thmajor origin of hepatic myofibroblasts. Although many therapeutic interventions are effective in experimental models of liver fibrosis, their efficacy and safety in humans is unknown.

Key Words: *Myofibroblast, Liver, Fibrosis, Hepatic, Fibroblasts*

Introduction to Liver Fibrosis

Liver fibrosis represents a major worldwide health care burden (1). It represents a significant health problem worldwide of which no acceptable therapy exists (2) and not just that, liver fibrosis is a major cause of morbidity and mortality worldwide due to chronic viral hepatitis and more recently from fatty liver disease associated with obesity (3).

Liver fibrosis is the excessive accumulation of extracellular matrix (ECM) proteins including collagen (scar tissue) that occurs in most types of chronic liver diseases (4-6).Advanced fibrosis results in cirrhosis and is characterized by an accumulation of extracellular matrix (ECM) rich in fibrillar collagens. Although various types of collagen are involved in liver fibrosis, type IV is said have a major role (7). It results in liver failure and portal hypertension and is associated with an increased risk of liver cancer (2). Progressive liver fibrosis is the main cause of organ failure in chronic liver diseases of any etiology. The accumulation of ECM proteins distorts the hepatic architecture by forming a fibrous scar and the subsequent development of nodules of regenerating hepatocytes defines cirrhosis (5,8). Cirrhosis will in turn result in hepatocellular carcinoma (9). Myofibroblasts are the cells which form the extracellular matrix (mainly Type-1 collagen fibres), which is responsible for the fibrous scar in liver fibrosis (10, 11). The main causes of liver fibrosis and cirrhosis in industrialized countries include chronic HCV infection, alcohol abuse and nonalcoholic steatohepatitis (NASH) (5, 12). Advanced liver fibrosis results in cirrhosis, liver failure and portal hypertension and often requires liver transplantation. It is considered that hepatic stellate cells (HSC's) and myofibroblasts play a major role in liver fibrosis.

Stages of Liver Damage

The following are the stages of liver damage or failure (13):-

Stage 1. Fatty Liver

Stage 2. Liver Fibrosis

Stage 3. Liver Cirrhosis

Stage 1. Fatty Liver

In this stage, there is excessive fat accumulation. This may usually be due to chronic alcoholism. This prevents the breakdown of fat which ultimately gets accumulated in large amount and casue liver enlargement.

Stage 2. Liver Fibrosis

As already stated above there is excessive accumulation of extracellular matrix proteins including collagen. In detail, this topic will be discussed below.

Stage 3. Liver Cirrhosis

Long standing liver fibrosis will result in liver cirrhosis. This will result in reduced or retarded liver function along with reduced blood supply causing death of liver tissues and ultimately liver failure.

Liver Fibrosis- Mechanism

As already disccused above, liver fibrosis is due to abnormal proliferation and accumulation of fibrous connective tissue (scar tissue) in the liver (14). It is quite normal for our body to undergo healing process in reponse to an injury and result in scar tissue formation. But in fibrosis, there is chronic or increased activation of this scarring tissue formation i.e collagen deposition. This is stimulated by a wide variety of factors such as chronic alcohilsm, the most common factor, others include chronic infection by hepatitis B, C viruses and parasite Schistosoma, certain drugs and toxins, infections, non-alcoholic steatohepatitis (NASH), inherited disorders like Wilson's disease, α-1 antitrypsin deficiency, autoimmune diseases, etc (14,15). It begins with the stimulation of chemical messengers such as cytokines, etc which will activate hepatic stellate cells (HSCs) which in turn will cause synthesis of collagen, glycoproteins, etc. All this along with the impairment of collagenolysis will result in increased extracellular matrix deposition resulting in liver fibrosis.

Stages Of Liver Fibrosis

The following are the stages in liver fibrosis (13) :-

Stage 0: which indicates no fibrosis.

Stage 1: which indicates enlargement of the portal areas by fibrosis.

Stage 2: which indicates fibrosis extending out from the portal areas.

Stage 3: which indicates a stage of fibrosis that link up portal and central areas of the liver.

Stage 4: which indicates liver cirrhosis.

Hepatic Stellate Cells (Hsc's)

These cells play a major role or infact are responsible for liver fibrosis. They are also known as fat-storing cells and generally represent 5-8% of all healthy liver cells (14). These cells are mainly located near the hepatocyte in the perisinusoidal space of Disse by means of their dendritic cytoplasmic processes extending along and around endothelial cells. Basically, they exhibit two phenotypes- quiescent and activated hepatic stellate cells. Quiescent HSC's are star shaped and their cytoplasm contains various components like lipid droplets, which contain retinoids, triglycerides, cholesterol, and free fatty acids . In fact, storage and limited release of retinoids is a major function of HSC in the healthy liver. A number of stimuli such as chronic alcohilsm, viral infections, etc, as already discussed above, will stimulate the conversion of quiescent to active HSC's. These cells later develop into myofibroblast-like cell types, which is carried out mainly by the loss of lipid droplets and other features such as lack of glial fibrillary proteins and increased proliferation of cells (14, 17).

Molecular Basis Of Liver Fibrosis

Liver fibrosis is basically a resultant of increased collagen deposition and decreases collagen destruction which in turn results in increased extracellular matrix.

It has two main phases- inflammation and fibrogenesis (14). Hepatotoxic factors like alcoholism, etc induces the synthesis of chemical mediators like cytokines, etc which will cause inflammatory reactions within hepatic cells converting them into active HSC's from quiescent HSC's (14). These activated HSC's, during their transformation process, becomes proliferative and morphologically begins to appear like myofibroblasts, which are devoid of lipid droplets, lack glial fibrillary-acidic protein and cause excessive production of ECM components (14).

Activated HSCs migrate towards regions of injury, in reponse to the chemical messengers

released from the site of injury and start accumulating around damaged tissue. Activated HSCs express the following : cytoskeleton protein, α-smooth muscle actin (α-SMA) and various connective tissue proteins including collagen types I, III, and IV (14,18-20). In addition to all of the above, liver fibrosis exhibits increased levels of tissue inhibitors of matrix metalloproteinases (TIMPs). These in turn are capable of inhibiting the action of MMP-1 (interstitial collagenase), thereby causing the accumulation of collagen fibers.

Myofibroblasts

Myofibroblasts are another group of cells that also play a major role in liver fibrosis. They are a unique group of smooth-muscle-like fibroblasts that have a similar appearance and function. In other words they are alpha smooth muscle actin positive cells. Through the secretion of extracellular matrix proteins (including fibrillar collagen) and proteases, they play a very important role in liver fibrosis and organogenesis, oncogenesis, inflammation repair in most organs and tissues. That produce extracellular matrix proteins. Myofibroblasts are the cells that are prominent in liver fibrosis (21-23).

They are generally characterized immuno-phenotypically by spindle or stellate shape, pale eosinophilic cytoplasm, expression of abundant pericellular matrix and fibrotic genes (vimentin, a-smooth muscle actin (a-SMA), non-muscle myosin, fibronectin and collagen Type I). Ultrastructurally, myofibroblasts are defined by prominent rough endoplasmic reticulum, a golgi apparatus producing collagen, peripheral myofilaments, fibronexus (no lamina) and gap junctions . In liver fibrosis, the myofibroblasts are imbedded in the fibrous scar. (21-23)

In both experimental and clinical liver fibrosis, there is a close correlation between the regression of liver fibrosis and the disappearance of these myofibroblasts. There is a general fact that these myofibroblasts are ultimately responsible or act as the source of excessive extracellular matrix proteins in liver fibrosis. Therefore, identifying the origin of these myofibroblasts will provide information about the pathology of liver fibrosis and perhaps even about new therapeutic targets.

Origin of Myofibroblasts

The origin of myofibroblasts in liver fibrosis is stillquestionable and debatable, although morphologic evidence has suggested that they are derived from fat storing cells-lipocytes (24).

There are at least three potential sources of myofibroblasts in the liver:

1. Resident mesenchymal cells (consisting of the quiescent hepatic stellate cell and portal fibroblasts).
2. Hepatocytes, cholangiocytes and endothelial cells.
3. The bone-marrow derived cells.

1. Resident Mesenchymal Cells (The Quiescent Hepatic Stellate Cells – Hsc And The Tissue Fibroblasts)

The resident mesenchymal cells, which mainly consists of the quiescent hepatic stellate cells (HSC) and the tissue fibroblasts, can become myofibroblasts. These cells are characterized by cell markers like CD45-, CD34-, desmin+, glial fibrillar associated protein (GFAP)+ and thy-1+ (25). Fibroblasts are primarily located in the portal tract in the normal liver (26,27). Recent studies (28) had demonstrated that thy-1 is a potential marker of activated myofibroblasts in the injured liver. Many studies have demonstrated an overlap in experimental fibrosis between thy-1 and alpha smooth muscle actin, indicating that some myofibroblasts are derived from fibroblasts in liver fibrosis. Studies from other researchers have proposed that TE-7 (Human Thymic Fibroblasts Antibody), an antibody against elastin, specifically identifies fibroblasts in the liver (29,30).

As already stated above, generally in a normal liver, HSCs reside in the space of Disse and they are the major storage sites of vitamin A. Following a chronic injury, hepatic stellate cells activate or gets transdifferentiated into myofibroblast-like cells, acquiring the contractile, pro-inflammatory and fibrogenic properties. These activated HSCs will migrate and accumulate at the sites where tissue repair is required, start secreting large amounts of ECM and regulate ECM degradation (31,32).

Those myofibroblasts which are derived from small portal vessels will proliferate around biliary tracts in cholestasis-induced liver fibrosis in order to initiate collagen deposition (23,

33) HSCs and portal myofibroblasts differ in specific cell markers and response to apoptotic stimuli (34). Several markers have been proposed to be specific for hepatic stellate cells, whether in the quiescent or activated state. These markers include florescence of Vitamin A in lipid droplets, GFAP, p75 NGF receptor, and synaptophysin (35-37). Using these markers, it is possible for one to distinguish between myofibroblasts that originate from fibroblasts or from hepatic stellate cells in experimental liver fibrosis.

2**. Bone-Marrow Derived Cells (Fibrocytes And Circulating Mesenchymal Cells)**

Bone-marrow derived cells, consisting of fibrocytes and circulating mesenchymal cells, can also be recruited to the injured liver to become myofibroblasts. These cells are CD45+ (fibrocytes), CD45+/- (circulating mesenchymal cells), collagen type I +, CD11d+ and MHC class II+.

Culture of CD34+CD38– hematopoietic stem cells with various growth factors has been shown to generate HSCs and myofibroblasts of bone marrow origin that infiltrate human livers undergoing tissue remodelling (38,39). These data suggest that cells originating in bone marrow can be a source of fibrogenic cells in the injured liver.

3. **Hepatocytes, Cholangiocytes, And Endothelial Cells**

Few reccent studies have proposed the fact that hepatocytes, cholangiocytes, and endothelial cells can actually become myofibroblast through epithelial or endothelial mesenchymal transition (EMT). These cells include CD45-, albumin+ (i.e. hepatocytes), CD45-, CK19+ (i.e. cholangiocytes) or Tie2+ (endothelial cells) (25).

Anti-Fibrotic Drugs And Liver Fibrosis

The high prevalence of insults with the potential to cause liver fibrosis, including chronic viral hepatitis, non-alcoholic steatohepatitis, toxic damage through alcohol consumption, etc indicates that fibrosis and cirrhosis of the liver remain major causes of morbidity and mortality worldwide (40). Hepatic Fibrosis and cirrhosis represent the consequences of a sustained wound healing response to chronic liver injury from a variety of causes including viral, autoimmune, drug induced, cholestatic and metabolic diseases (41).

Extensive research is being conducted and performed primarly to understand the mechanisms responsible for the development of liver fibrosis. Few drugs of liver fibrosis are effective in experimental models but their safety and efficacy in case of humans is questionable.

Conclusion

Liver fibrosis represents a significant health problem worldwide and is a major cause of morbidity and mortality across the globe. From the above, it can be concluded that liver fibrosis is a very complex disease. Not just medical professionals but even the general population should be made aware of this medical condition. Hence, in that aspect this article will be useful in understanding about liver fibrosis.

Local Anaesthesia Failure in Endodontics

Anandadeeban K B S [1], Balakrishna [2]
Graduate Student [1], Senior Lecturer [2],Department of Oral and Maxillofacial Surgery
Saveetha Dental College, Saveetha Institute of Medical and Technical Science,
Saveetha University, Chennai,India

Abstract

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage Local anaesthesia is essential for successful completion of endodontic treatment. Although pain treatment is well managed in many endodontic patients, there exists a group of patients who do not receive adequate local anaesthesia inspite of proper administration of local anaesthesia.This article reviews about the reasons for failure of local anaesthesia during endodontic treatment.

Key Words:Local anaesthesia,pain,mandibular molars, inflammation

Introduction

During dental procedure localanaesthesia plays a major role in controlling the pain.They are the safest and most effective drugs in all of medicine for the prevention and management of pain during dental procedure.Extraction of teeth, root canal treatment, minor surgical procedures and periodontal procedures,tooth preparation mandatorily need administration of a local anaesthetic in order to minimize patient discomfort and make patient co-operative during dental treatment[1]. Fear of pain is the main issue which causes patients to refuse dental treatment. Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage. This discomfort signals actual or potential injury to the body[2].The success of local anaesthetic administration depends on various factors like such as site of administration if local anaesthesia, injection techniques, dosage and allergic complications. Many studies saysthat local anaesthetic failures are more likely to occur because of choosing improper.site for injection and inappropriate techniques to administer it.. [3].

It has been estimated that about 20% of patients experience moderate- to- severe pain after treatment [4].Very few patientswill experience a sudden ‘flare- up’ of severe pain or swelling after endodontic treatment has been over. Thus clinical management of endodontic patients is often problematic due to inadequate local anaesthesia.

Various Reason for Failure of Local Anaesthesia

1) Anatomical Factors

Few suggest that the inability of the operator to load the localanaesthesia in close proximity to the corresponding nerve would lead to inadequate blockade in both normal and uninflamed states, it may be possible that a partial blockade would be adequate in neurons that were not sensitized by inflammatory mediators. Thus, it is important to know the nerve supply to the tissue to be anesthetized, as well as the anatomy of the injected site and its variations present.Anatomic variation would have a lesser impact on infiltration anaesthesiawhich is commonly used in maxilla.

Usually, the pulps of mandibular teeth will anesthetized by blocking of the inferior alveolar nerve via an intraoral approach to deliver the local anaesthetic to the pterygomandibular

space. In the classic technique, the needle is advanced to a point where a pool of anaestheticis deposited near the mandibular foramen, which lies below the lingula, and in the sulcus colli mandibulae[5]. As the bony prominence of the lingula projects medially, it is often difficult to place the tip of the needle in the sulcus colli, and it has been suggested that the bevel should be orientated towards the midline in order to take advantage of the lateral deflection that would be provide via tissue resistance . However, even when needle placement is given with proper technique there occur the failures of local anaesthesia.This may be due to the erratic post- injection distribution of anaesthetic solution in the pterygomandibular space over which the operator has no control [6]

Accessory innervation to the mandibular teeth from several sources has also been known as the cause for inadequate localanaesthesia. In particular, the nerve tothe mylohyoid muscle has been implicated in carrying afferent fibers from the mandibular teeth. In a study of 37 cadavers, it has been found the point at which the mylohyoid nerve branched from the inferior alveolar nerve to be an average of 14.7mm above the foramen of mandible a distance which is sufficient to prevent a blockade of the mylohyoid nerve when the classic technique is used. To overcome accessory innervation from the mylohyoid nerve, the clinician has several options, including the use of a block technique that deposits anaesthetic solution higher in the pterygomandibular space (i.e. Gow- Gates or Akinosi), infiltration on the lingual surface of the mandible adjacent to the tooth operated, or techniques that deposit anaesthetic solution in the medullary space surrounding the operated tooth, such as the intraligamentary or intraosseous routes of injection.Lingual nerve, buccal nerve are the other nerves which gives stimulus to the mandibular teeth.Regardless of the origin, the technique that would predictably block allsources of accessory innervation to the mandibular teeth would be one in which the anaesthetic solution is deposited at the apices of the teeth in question (i.e. intraligamentary or intraosseous routes). Even though both of these techniques appear to increase the efficacy of inferior alveolar block anaesthesia, research show a greater duration of lower molar pulpal anaesthesia (as determined by a reading of 80 on an electric pulp tester) to be provided by the intraosseous technique [7].

2. Effect of Local Tissue Inflammation.

Usually local anaesthetics diffuse through the cell membrane and then block the sodium channel by accessing the protein from the cell's cytoplasm. This action requires the shift of

drug between its acid form (an ionized or charged molecule) and its base form (an uncharged molecule). The pH of most local anaesthetics in cartridge form is purposefully low (pH = 3–4), because the charged, acid form of the molecule is more stable (as is the vasoconstrictor) at a low pH, and thus gives a longer shelf life [8].Once injected, the local tissue pH and the drug's strength as an acid regulate the distribution of the local anaesthetics between the acid and base forms according to the well- known Henderson- Hasselbalch equation.The proportion of the drug that exists in the uncharged base form is available to diffuse across the cell membrane. As it enters the cell, the drug repartitions into the acid and base forms, and it is the acid form of the drug that blocks the sodium channel.

This becomes as an potentially important issue because inflammation- induced tissue acidosis may cause ‘ion trapping’ of local anaesthetics. According to this hypothesis, the low tissue pH will result in a greater proportion of the local anaesthetics being trapped in the charged acid form of the molecule and, therefore, unable to cross cell membranes. This has been advanced as a major mechanism for failures of local anaesthesia in conditions such as endodontic pain .The reduction in tissue pH results in a substantial proportion of the drug being trapped in the charged acid form. Thus, over the pH range of 7.4–6.6, in comparison to lidocaine or bupivacaine, mepivacaine is relatively resistant to ion trapping. To the extent that this hypothesis explains local anaesthetics failure, mepivacaine represents a logical local anaesthetics for use in patients with irreversible pulpitis.

The relationship between the proportions of local anaesthetics in the cationic acid form of the drug as a function of tissue pH. Note that the cationic acid form cannot diffuse across cell membranes and is referred to as the ‘ion trapped’ proportion of the molecule. This proportion is derived from the Henderson- Hasselbach equation and the pKa value for each drug.

However, there are considerations that may limit the local pH hypothesis. First, the acidosis may be minor in magnitude. Although severe forms of liquefaction necrosis may have pH levels as low as 4 to 5, the affected area is restricted to the actual abscess. Studies on cutaneous inflammation indicate that tissue pH may be only marginally reduced to pH values of about 5.8–7.2 [9]. In addition, inflamed tissue possesses greater buffering capacity than normal tissue (possibly due to extravasation of protein or erythrocytes into the inflamed tissue). Thus, the actual pH change may not be large enough to produce substantial ion trapping of local anaesthetics. In addition, a reduction in tissue pH is likely to be a localized event and, with the exception of mandibular second and third molars, most probably does not

involve distinct facial space compartments that isolate the site for an IAN nerve block from the mandibular teeth. Thus, even in severe forms of inflammation, local tissue pH may explain problems with infiltration anaesthesia in maxillary teeth, but is unlikely to explain local anaesthetics failures in nerve block anaesthesia.

To the extent of its validity, the local pH hypothesis has at least two clinical implications. Firstly, it suggests that local anaesthetics with lower pKa values are likely to be more effective in endodontic pain patients. This recommendation is based on the physical properties and available formulations of these drugs, and it should be evaluated in a prospective clinical trial. Secondly, the temporary adjustment of tissue pH may be used to augment clinical anaesthetics. This strategy has been employed by anaesthesiologists with sodium bicarbonate to alkalinize the local anaesthetics and tissue pH and thereby enhance local anesthesia. Addition of sodium bicarbonate also raises the pCO2 of the anesthetic solution bathing the nerve. When CO2 crosses the nerve membrane and decreases the intracellular pH, the ionized form of the drug is favoured, and as mentioned previously, it is this form that binds to the sodium channel to effect blockade.

Although alkalinisation may have theoretical utility, there is a paucity of clinical trials in dental pain patients to support its use. In one study, compared with a standard lidocaine formulation, a buffered lidocaine formulation demonstrated no significant difference when given by infiltration injection into inflamed maxillary incisors [10]. Although other formulations may warrant testing in additional studies, there does not appear to be a preponderance of clinical evidence to support the use of alkalinisation of local anesthetic solutions

3.Effect of Inflammation on Central Sensitization

Inflammation also induces changes in the central nervous system's pain processing system. Activation and sensitization of nociceptors in pulpal and periradicular tissue results in a barrage of impulses sent to the trigeminal nucleus and brain. This barrage, in turn, produces central sensitization. Central sensitization is the increased excitability of central neurons and is thought to be a major central mechanism of hyperalgesia [11]. Under conditions of central sensitization, there is an exaggerated CNS response to even gentle peripheral stimuli. A common example to this is sunburn, where even the innocuous stimulation of wearing a t- shirt is considered painful. Similarly, percussing a tooth with an inflamed periodontal

ligament (e.g. acute apical periodontitis) may produce an exaggerated pain response which is due, in part, to central sensitization.

Although we often consider central sensitization when discussing endodontic pain mechanisms (65), this same process may contribute to local anesthetic failures. Under normal conditions, many patients tolerate dental procedures, even though a slight or occasional sensation may still be felt. In other words, under normal conditions, a local anesthetic injection that blocks most of the fibers (say, 90%) may still be clinically successful. This has been reported in other clinical models (for example, IV cannulation of the arm), where patients treated with a topical anesthetic reported that they did not experience pain, even though their visual analog pain scores were greater than zero [12]. However, under conditions of central sensitization, there is an exaggerated response to peripheral stimuli and, under these conditions, the same 90% block may permit sufficient signaling to occur to lead to the perception of pain. Thus, central sensitization may contribute to local anesthetic failures.

Unfortunately, there are no selective drugs for blocking central sensitization. The only clinical implication would be to reduce the afferent barrage and thereby reduce central sensitization. This is done routinely by clinicians via cleaning and shaping techniques, but this is a conundrum, as the endodontic treatment is performed after local anesthesia. One interesting study has demonstrated that intraosseous injection of steroid (methylprednisolone acetate 40 mg) reduces endodontic pain in 24 h . If confirmed, then this approach may reduce peripheral and central mechanisms sufficiently to obtain predictable local anesthesia.

4.Psychological Factors

Patient anxiety may also contribute to local anesthetic failure. Experienced clinicians understand that apprehensive patients have a reduced pain threshold and are more likely to report an unpleasant dental experience [13] Fear of seeing and/or feeling the needle and the sound of the dental handpiece are routinely cited as causative agents in the creation of anxiety in the dental patient. Moreover, patients may be particularly anxious about impending root canal therapy. Investigators have also demonstrated that patient anxiety predicts a poor outcome for clinical procedures involving local anaesthetics applied to the arm before IV cannulation .Thus, patient anxiety should be considered when managing the endodontic pain patient.

Several methods have been advocated for managing anxious emergency pain patients. First, the clinician should establish a positive and confident relationship and avoid exposing the

patient to obvious fear- producing stimuli. Many clinicians report that a sense of humor often helps to relax apprehensive patients. For extremely fearful patients, cognitive behavior- based programs have shown significant long- term reduction in predental treatment anxiety. Other studies have demonstrated that instructing patients to focus on sensory stimuli significantly reduces intraoperative endodontic pain. This effect was most evident in patients who were characterized as having a high desire for control and a low perceived control over their clinical care.

Second, pharmacologic agents can be administered to control patient anxiety. While these agents can be delivered via oral, inhalation (N2O) or intravenous routes, a decreased likelihood of serious morbidity, reduced monitoring and demonstrated efficacy have made oral or a combination of oral and inhalation routes attractive [14]. Kaufman et al showed that oral triazolam 0.25 mg was equally effective in comparison to intravenous diazepam in reducing anxiety in patients undergoing oral surgery.

One could certainly consider an integrated approach that involves both non- pharmacologic and pharmacologic techniques. Regardless of the technique utilized, providing some means of anxiety control should enhance the clinician's ability to provide adequate local anesthesia for endodontic pain patients.

5. Acute Tachyphylaxis of Local Anaesthetics

It is well known in pharmacology that administration of receptor agonist drugs often leads to reduced responsiveness to a subsequent administration of the drug,an effect called tachyphylaxis. Since local anaesthetics are often administered together with vasoconstrictors, there is the possibility that the drug persists in the tissue for a sufficient amount of time to produce tachyphylaxis at the sodium channel. It has been proposed that this contributes to reduced anesthetic effectiveness, especially after repeated injections.

However, it is not clear that local anaesthetics produce substantial, or in fact any, tachyphylaxis under clinical conditions. Several clinical trials have evaluated repeated or continuous local anesthetic administration to treat chronic pain patients. Despite continuous infusion or daily administration for periods of up to several years, these studies have not reported tachyphylaxis to local anaesthetics[15].Thus, this hypothesis may have comparatively little merit for explaining local anesthetic failures.

6. Effect of Nociceptors Inflammation

Substances released from inflamed tissue have two major effects on nociceptive (‘pain detecting’) neurons [16]. Firstly, they change the functional activity of these neurons. As might be expected, nociceptors are thought to be quiescent throughout much of our lives and only discharge in the presence of stimuli strong enough to damage the tissue or chemicals that stimulate receptors on these neurons. Inflammatory mediators activate or sensitize these neurons by interacting with specific receptors. An example of a mediator that activates nociceptors is bradykinin: its administration causes a brisk firing of unmyelinated C nociceptors via activation of cell surface bradykinin receptors (BK1 or BK2). Prostaglandin E2 is an example of a mediator that sensitizes nociceptors: administration of PGE2 reduces the threshold for firing to the point where gentle stimuli can now activate these neurons. For example, the throbbing nature of pulpal pain is thought to be due to pulpal nociceptors sensitized to the point where they discharge in response to the patient's heartbeat. Thus, activation and sensitization are two major mechanisms by which inflammatory mediators alter the activity of these normally quiescent neurons. Although local anaesthetics display use- dependent blockading properties, peripheral sensitization and activation have been reported to cause an increase in the resistance of nerves to anaesthetics.

In addition, inflammatory mediators, including certain growth factors, have profound effects on these neurons by altering their structural properties. In particular, the elegant studies by Byers and her colleagues have led to the realization that the terminals of peripheral nerves literally grow (‘sprout’) into areas of inflammation in dental pulp and periradicular tissue ([17]. Clinical studies have confirmed that a similar sprouting occurs in inflamed human dental pulp. This increase in nerve terminals in inflamed tissue increases the size of their receptive field, indicating that pain neurons may now be more easily activated by a spatial summation of stimuli.

Inflammation also changes the synthesis of several proteins in nociceptors, leading to an increase in neuropeptides, such as substance P and calcitonin gene- related peptide. These neuropeptides play important roles in regulating pulpal inflammation. In addition, tissue injury may alter the composition, distribution or activity of sodium channels expressed on nociceptors. The effect of inflammation on these sodium channels may have profound implications in local anesthetic failures.

Several types of sodium channels have been discovered over the last decade. One particular group of channels is characterized as being resistant to the puffer fish toxin, tetrodotoxin (TTX). At least two channels are members of the TTX- resistant class, including the PN3

(also known as SNS, or NaV 1.8) and NaN (also known as the SNS2 or NaV 1.9) sodium channels. The TTX- resistant class of sodium channels is of interest since they are less sensitive to lidocaine [18]. The TTX- resistant class of sodium channels is expressed on nociceptors under normal conditions. In addition, their activity more than doubles after being exposed to prostaglandin E2.Thus, we hypothesize that the TTX- resistant class of sodium channels represents a logical mechanism for local anesthetic failures: the channels are relatively resistant to lidocaine, they are expressed on nociceptors, and their activity is increased with PGE2.

7.Effect of Inflammation on Blood Flow

Inflammation has several other effects on local tissue physiology. For example, it has been proposed that peripheral vasodilation induced by inflammatory mediators would reduce the concentration of local anaesthetics by increasing the rate of systemic absorption [19].This is a potentially important mechanism, because local anaesthetics are well- recognized vasodilators that, in most cases, require formulation with vasoconstrictor agents. Although inflamed dental pulp experiences regional changes in blood flow, less is known about inflammation- induced vascular changes in periradicular tissue. Moreover, it is likely that this vasodilation may be localized and not evident at distant sites of injection (i.e. nerve block injection sites). Thus, this hypothesis may have greater utility in explaining difficulties with infiltration anesthesia when compared with nerve block anesthesia.

To the extent that this hypothesis predicts local anesthetic failure, there are clinical implications that may improve the success of local anesthesia. If vasodilation leads to increased drug absorption, then the use of higher concentrations of vasoconstrictors may produce more profound or longer duration anesthesia. Thus, in patients who can tolerate it, the use of 1:50000 epinephrine may improve clinical success in anesthetizing patients with endodontic pain. However, to date, the results from clinical trials have been equivocal. The use of 1:50000 epinephrine produces a greater degree of vasoconstriction in patients than 1: 100000 epinephrine [20]and yet, there is no difference in the magnitude or duration of clinical anesthesia in normal subjects .In this latter study, the clinical anesthesia for 2% lidocaine was the same, regardless of whether the epinephrine was present at 1:50000, 1:80000 or 1:100000 . Knoll- Kohler and Fortsch, however, showed a dose- dependent relationship between the onset and duration of anesthesia and the concentration of epinephrine(1:200000, 1:100000, 1:50000) when used with 2% lidocaine for infiltration

anesthesia [21].It should be noted that these studies were conducted in normal subjects and, to date, no clinical trial has tested whether these higher concentrations of epinephrine alter anesthesia in endodontic pain patients in whom tissue vasodilation may be increased.

Conclusion

Analgesia is essential for successful completion of modern dental procedures. Difficulty experienced in obtaining satisfactory analgesia after proper administration especially of an acutely inflamed mandibular molar, remains a common clinical problem. This article reviews about the various reason for failure of local anaesthesia during endodontic procedure.

Abstract

The involvement of macrophages in chronic inflammatory conditions hasbeen the subject of considerable experimental investigation in recentyears. Macrophages are able to secrete a wide range of biologically activecompounds. They are important in the control of infection and, throughtheir immunological and non-immunological receptors; macrophagesinteract with other cell types and a wide variety of proteins.Monocyte proliferation is apparent in a number of disorders, includingcollagen diseases, many infectious diseases, neo-plastic conditions andchronic inflammatory gastrointestinal diseases. Macrophage dysfunction may also result from adrenocorticosteroidadministration or exposure to ionising radiation.Macrophage cell function has been extensively investigated in disorderssuch as lepromatous leprosy, miliary tuberculosis, disseminated fungalinfections and in Hodgkin's disease. Intrinsic or acquired functionaldefects, however, have not been convincingly proved in these conditions.Recent information on the tissue damaging potential of compoundsreleased from activated macrophages has focused interest on a wide varietyof chronic inflammatory conditions where macrophages may potentiatetissue damage in a non-specific manner.The purpose of this review is to highlight recent advances concerningmacrophage origin, function and toconsider how far macrophages may be involved in the promotion ofinflammation in a variety of diseases.

Key Words: *Macrophage, Monocyte, Immunity, Blood, Defense.*

Introduction

The blood consists of monocytes from which the tissue macrophages develop. The capacity of both monocytes and tissuemacrophages to proliferate is limited, and therefore the provision ofadequate numbers of macrophages, especially at an inflammatory focus isdependent upon delivery of blood monocytes. Circulating bloodmonocytes are derived from a rapidly proliferating precursor pool of cellsin the bone marrow, termed promonocytes. The same basic stem cell maygive rise to either monocytes or granulocytes and differentiation iscontrolled by specific colony stimulating factors derived from monocytes,lymphocytes or endothelial cells.

Macrophages are myeloid immune cells. They are present throughout thebody tissues and have the function of ingesting and degrading dead cells, debris and foreign material. They also facilitate the inflammatory processes. Most of the tissue-resident macrophages are formed prenatally and reach until adulthood by their longevity and self renewal properties.The development and maintenance of macrophages maybe independent from the process of haematopoiesis, but the cells may develop alongside the adult monocyte-derived macrophages. Aside from being immune sentinels,tissue macrophages form integral components of their host tissue. Thus these cells are able to respond to the local environmental factors. By this method, it helps in the development and specialized functioning of the host tissue. Factors that govern tissue macrophagespecialization are emerging. Tissue specialization is due to gene expression of the macrophages.

Macrophages are myeloid immune cells that are characterized by avid phagocytosis.Very befittingly, Ilya (Eli) Metchnikoff, the father of cellular immunology, hence referredto these cells as ‘the big eaters’ in Greek [1]. With extraordinary intuition Metchnikoff, atrained comparative zoologist, foresaw the fascinating biology of macrophages and theircentral role in health and disease states and was rightfully awarded a Nobel Prize.Using intra-vital microscopy to visualize macrophage swarms in pricked starfish larvaeand infected water fleas, Metchnikoff noted the striking similarities of invertebratephagocytosis and vertebrate blood cells. He proposed that macrophages had originallyevolved to regulate development through phagocytosis of unwanted or obsolete cells,such as in the pruning of digits and frog morphogenesis. Activities of these professionalphagocytes might then have been recruited for innate immune effector

functions,including pathogen clearance. Importantly, beyond regulating development andcontrolling pathogens, Metchnikoff also recognized that macrophages play a major roleduring injury repair and appreciated their contribution to sterile ‘physiological’inflammation [1]. He thereby anticipated the role of inflammation and macrophages inhomeostatic maintenance processes of the healthy organism, very much in line withcurrently held views [2, 3].

Development of Macrophages

Macrophages have been classified as part of the mononuclear phagocyte systemestablished by Van Furth and Cohn [4, 5], alongside with monocytes and dendriticcells (DC), that were included upon their discovery by Ralph Steinman in the mid 1970s[6-8]. The mononuclear phagocyte concept [5] proposed that tissue-residentmacrophages rely in adulthood on replenishment by bone-marrow (BM)-derived bloodmonocytes. However, the notion of an inherent developmental link between tissuemacrophages and blood monocytes has remained disputed throughout the years [9].Long-term persistence of adult tissue macrophages relying on self-renewal is well established. Moreover, certain embryonic macrophage populations are establishedbefore the emergence of circulating monocytes. Finally, monocytopenic animals displayseemingly normal tissue macrophage compartments and tissue-resident macrophagenumbers are also largely unaffected in human patients suffering from monocytopenia.Collectively, these findings motivated fate mapping experiments to addressmacrophage origins and that revealed the major alternative, non-monocytic origin ofthese cells and thereby corrected the notion of an obligatory steady state monocytemacrophageaxis.The revised concept of the mononuclear phagocyte system, though still mainly basedon data from the mouse, now accommodates the existence of tissue macrophages oftwo distinct origins. (1) The majority of macrophages that reside in healthy tissue areestablished prenatally. These cellular compartments self-maintain locally independentfrom each other within their tissue of residence and are self-sufficient and independentfrom further hematopoietic input. (2) In addition, macrophages can develop in adulthoodfrom tissue-infiltrating monocytes. This pathway is associated with pathological, but alsohomeostatic inflammatory reactions. Monocyte-derived macrophages generally displaylimited life spans, although exceptions have been reported. Embryonic- and adultderivedmacrophages can co-exist

in given tissues and their respective abundancelikely reflects the nature and history of their tissue of residence. Whether embryonicandadult-derived macrophages differ with respect to functional contributions inhomeostasis or following challenge, remains however to be shown and a key questionwith major clinical relevance.

The different types of Macrophages are,

- **Prenatally established tissue macrophages**

Embryonic macrophages

Adult tissue macrophages of embryonic origin

- **Postnatally-generated tissue macrophages**

Monocytes - the precursors

Monocyte-derived macrophages in pathology-associated Inflammation

Monocyte-derived macrophages in homeostatic inflammation

Functions of Macrophages

The mononuclear phagocyte system is involved in five major areas: (a)defense against microorganisms, (b) removal of dead or damaged cells, celldebris and inorganic material, (c) regulation of haematopoiesis, (d)cooperative and effector functions in the immune response, (e) synthesis ofbiologically active compounds such as complement components, prostaglandins,interferon and neutral proteases.

These other functionsof the macrophage may, however, be highly relevant to infections, allergicand autoimmune mechanisms in inflammatory bowel and liver disease, andto the development of immunological abnormalities such as the hyperglobulinaemiaof liver disease.

Defense against Microorganisms

Macrophages are the principal cells involved in killing intracellular parasites such as mycobacteria, toxoplasma and cryptococci [10-12].Macrophage activation was a term used to describe the enhancedbactericidal properties of macrophages previously exposed to intracellularbacteria [13]. This term has now adopted a wider meaning.Macrophages must be able to show effective ability of chemotaxis, phagocytosis and also intracellular killing so that they can be efficient tools in killing the microorganisms. Monocyte chemotaxis is slow in

comparison withneutrophil movement. Chemotaxis is mediated by various enzymes such as the complementcomponents (C5b), the lymphokines and the various derivatives of phospholipids [14].Inhibitors of chemotaxis and inactivators are present in serum in differentdisease states [15, 16]. Once macrophages arrive at an inflammatory site, theyremain there under the influence of a lymphokine, migration inhibitionfactor which activates the cells and results in increased adherence. Thismolecule is probably identical to macrophage activating factor.Cells that have been exposed to a chemoattractant show enhancedexpression of surface complement receptors and are thus better able toadhere to opsonised particles [17]. Subsequent particle ingestion is an energydependent process involving the activation of actin binding protein, whichleads to actin polymerisation to microfilaments. These microfilamentsprovide the forces for pseudopod formation and particle engulfment [18].Particle ingestion depends on the surface receptors involved and the stateof activation of the cell.Macrophages possess multiple mechanisms for killing or degradingingested organisms. The various mechanisms by which macrophages kill the microorganisms includeproduction of hydrogen peroxide [19] and by the production of various oxygen derived products [20]. Myeloperoxidase and otherperoxidase activity [21] have been shown in these cells. Lysosomal fusion withthe phagaocytic vacuole suggests that cationic proteins, hydrolases andcatalases are also important in bacterial degradation [22, 23].

Removal of Damaged Cells, Debris and Inorganic Material

The mononuclear phagocyte system kills the erythrocytes which have been damaged by physical or chemical injury, surface carbohydrate alterations oraging [24]. Alveolar macrophages clear particulate matter from inspiredair [25]. Various inorganic materials such as beryllium, barium salts, zirconium and silica are localised within tissues, often within macrophages.

Regulation of Haematopoiesis

The substances with specific colony stimulating activity determine the formation of granulocyte and monocyte colonies in culture.Circulating monocytes and macrophages are the main source of colonystimulating activity in man [26]. Granulocytes are able to produce compoundssuch as lactoferrin, with colony-inhibiting activity. These compounds blockthe resting but not the activated production of colony stimulating activityby monocytes [27].Macrophages therefore control theproliferation of their own and other progenitor cells through both positiveand negative

feedback systems. Bone marrow macrophages have beenshown recently to influence the growth of early and late committederythoid precursors through the synthesis of soluble factors [28].

Macrophage Activation

The functional efficiency of the macrophage depends on its state of activation. The term 'activated macrophage' was introduced byMackaness [13] to describe the enhanced bactericidal properties ofmacrophages previously exposed to intracellular bacteria. In recent yearsthis term has been applied to describe a wide range of functional changes inthe macrophage, not necessarily resulting in increased bactericidal activity.Plasminogen activator which is a neutralproteinase, when it is secreted, it is seen to go hand in hand with the macrophage activation [29].

The induction of the synthesis and secretion ofplasminorn activator may depend on a number of sequential metabolicchanges [30]. The latter may occur earlier than those changes required for fullmicrobicidal activity. The macrophage activation can be best described by its function under study such as bactericidal, phagocytic or its metabolic activity [31]. Manyagents have been used to increase the yield of macrophages from theperitoneal cavity. Cells thus elicited show some of the features of activatedmacrophages, but not all the biochemical changes associated with fullyactivated cells are found [32].

Functional Specialization of Tissue Macrophages

Generic Macrophage Functions

Macrophages are as immune cells specialized in the phagocytosis and neutralization ofcellular debris and potentially hazardous agents, including pathogens. They can assuch be considered an adaptation of the multicellular organisms to cope with thechallenge arising from progressive cell specialization and complexity by outsourcingimmuno-surveillance to specialized phagocytes. Tissue macrophages are non-migratorycells that monitor their immediate, local environment, as strikingly visualized for microglia [33, 34]. Moreover, also many macrophage effector functions might beexpected to be concentrated on their closer surrounding. In this respect, macrophagescritically differ from highly mobile DC, which are also immune sentinels, but specializedin the triggering of remote T cell responses upon their trans-location to tissue-

drainginglymph nodes [8].To fulfill their role as guardians, tissue macrophages are equipped with a vastarray of sensing molecules, including scavenger receptors, pattern recognitionreceptors (TLRs, CLRs, RLRs, NLRs), nuclear hormone and cytokine receptors, as wellas adhesion molecules. The repertoire of these receptors though varies among tissuemacrophages and likely reflects local adaptation.Generic effector functions of macrophages include activities associated with their highlydeveloped lysosomal compartment that bears critical protease and bactericidal activity[35]. Moreover, macrophages play a critical role in the orchestration of theinflammatory reaction by provision of chemokines and cytokines that recruit and activate neutrophils, monocytes and lymphocytes. Macrophage activation andpolarization has been under intense study, mainly using in vitro system. Inresponse to challenge, macrophages also produce a plethora of effector molecules,including a battery of growth factors, such as PDGF (platelet-derived growth factors),IGFs (insulin-like growth factors), HGFs (hepatocyte growth factors), and FGFs (fibroblastgrowth factors).Expression of sensors renders macrophages responsive to changes in theirenvironment, but bears the inherent risk of macrophage hyper-activation and resultingcollateral damage. Counterbalancing their stimulation, macrophages are hence subjectto silencing programs that most likely set tissue-specific thresholds for their activationand allow the cells to gradually respond and gauge the quality and intensity of thestimulus. The exact nature of these silencing circuits differs between tissues andincludes innate inherent suppression, as well as acquired de-activation triggered inresponse to activating stimuli [36, 37].Of note, the robust silencing programs oftissue resident macrophages might necessitate the need of more plastic cells to copewith acute challenges. The latter seems to be accomplished through on demandrecruitment of monocytes, as flexible emergency squad [38].The immune sentinel task of tissue macrophages could arguably be performedby a stereotypic macrophage prototype, with minor adjustments to the particular tissuecontext. Surprisingly though, depending on their tissue of residence macrophagesdisplay highly distinct and characteristic gene expression signatures [39]. Collectively, these findings suggest that tissue macrophages exertbeyond their unifying features, functions associated with homeostasis of their particulartissue of residence. Of note, this is well compatible with the newly discovered fact thatthese cells develop alongside with their tissue of residence, rather than being eventuallyseeded.

Heterogeneity of tissue macrophages likely results from their adaptation tospecific host tissue environment and reflects a functional polarization governed by localtissue-derived signals; with

few exceptions, however, the identity of these signalsremains unknown. It is also unclear, whether functional heterogeneity is a resultof irreversible lineage-specific differentiation or a consequence of continuous, butreversible induction of diverse functional programs.

Tissue and Organ-Specific Contributions of Macrophages

Lung

The lung is the essential respiration organ and constantly exposed to microbes,pollutants and dusts. A prime task of the lung is to maintain a balance betweentolerances to inhaled innocuous stimuli, as well as the recently appreciated lung microbiome [40], while preserving the capability to mount an immune responseagainst opportunistic pathogens. Dysregulation of the response can lead to infectionsand sustained susceptibility to allergic airway inflammation. This challenge resemblesthat of the intestinal tract and indeed, both organs host equivalent innate immune cellsin the lamina propria, such as monocyte-derived macrophages[41]. In the lung, these cells are directly involved in acute immuneresponses, as well as tolerance induction [42].

Importantly, these macrophages are not located in the interstitial space,but in the alveoli of the healthy airways. Whether the reliance on embryonic originapplies to all lung macrophages remains to be determined.AM also excel in bacterial phagocytosis and produce significant amounts of typeI interferon upon pulmonary virus infection [43]. They thus contribute to thedevelopment of inflammation, but may also be involved in its resolution, since AMdepletion before bacterial or viral infections results in decreased pathogen clearance,but also in exacerbated inflammation [44, 45]. This restorative activity of lung AM canpotentially be explained by their robust anti-inflammatory phenotype, which needs to beovercome by the pathological stimuli. The unique microenvironment of the lung, as a classical environmentalbarrier tissue, significantly contributes to the phenotype of AM by providing factors thatcontrol hyper-activation and thereby govern the characteristic dampened tolerogenicimmunological response in this tissue.

Liver – Kupffer cells (KC)

The liver is a vital organ in charge of efficient uptake of nutrients, amino acids,carbohydrates, lipids and vitamins and their subsequent storage. It further promotesmetabolic conversion and

release of metabolites into the blood and bile, as well as thedetoxification of ingested hazardous chemicals. Liver lobules receive continuous bloodsupply from the arterial circulation and the portal vein, which drains the gastro-intestinaltract. The latter results in prominent liver exposure to food antigens, microbial productsand xenobiotics. The liver hence stars prominently in host defense and theestablishment of a local and systemic tolerance. Blood entering the hepatic parenchymapasses through a network of thin-walled ‘sinusoids’, which contain specialized nonparenchymalcells, also including a fenestrated layer of liver sinusoidal endothelial cells.These features confer effective antigen capture and presentation in thismicroenvironment [46]. KC, the resident macrophage population of the liver, is most abundant in theupstream periportal regions of the liver sinusoids. KC display high phagocytic andlysosomal activity, which highlights their specialization in the surveillance and filtering ofblood entering the sinusoids. They thereby form a protective barrier to prevent systemicpathogen circulation. In addition, KC remove potentially harmful endogenouscompounds, such as complement and fibronectin-coated particles, material releasedfrom dying cells and extracellular matrix components, as well as immune complexes toavoid intravascular coagulation. Despite their continuous exposure to gut-derivedantigens and bacterial endotoxins, and maybe because of the latter, KC exhibit in thehealthy liver a tolerogenic phenotype. However, under disease conditions, KC can shiftto a pathologically activated state and then cause hepatocellular injury and damage[47, 48].KC also performs liver-specific metabolic functions. KC furthermoreregulates plasma cholesterol levels through the removal of native and modifiedlipoproteins from the circulation. Specifically, they express receptors for both high-densitylipoproteins (HDLs) and low-density lipoproteins (LDLs), but are primarilyinvolved with the catabolism of LDLs and modified LDLs [48]. Kupffer cells areembryo-derived macrophages and the compartment seems to resists replacement byadult monocyte-derived cells during inflammation [49].

Bone – Osteoclasts

Bone is a unique, highly vascularized, rigid, yet dynamic organ designed to providemaximal strength with minimal mass. Bone shape is dictated by constant remodelinginvolving bone synthesis by mesenchymal osteoblasts and bone resorption byspecialized bone resident macrophages, the osteoclasts. Abnormalities in the balanceof osteoclast development or function,

relative to osteoblast activity, result in skeletalpathologies, such as osteopetrosis or osteoporosis [50]. Osteoclasts are moreoveressential for normal long bone formation during embryogenesis [51]. They aremultinucleated cells, or 'polykaryons', that form by cell fusion near the bone surface.RANKL is expressed by osteoblasts and induces polarization of mature osteoclasts, which is manifested in structural changes essentialfor their bone-resorption. This includes cytoskeletal rearrangements that enable theformation of a ruffled membrane structure and a “matrix attachment” sealing actin ringtowards the bone surface [52]. Pre- and post-natal osteoclast ontogeny remains poorly defined. Specifically, it isunclear whether osteoclasts originate from circulating blood monocytes or from bonetissue-resident precursors. The stimulus that recruits the monocytes tothe bones remains however to be defined.

Brain – Microglia

Microglia represents the tissue resident macrophages of the CNS and the sole residenthematopoietic, mesoderm-derived cell type in the CNS parenchyma. Microglia fulfillstwo main functions in the adult CNS: homeostatic maintenance and immune defense.Beside the neuronal circuitry, the CNS comprise of additional microglia populations,such as the myelin sheath-forming oligodendrocytes and astrocytes, which are involvedin physiological and biochemical tasks to functionally support the BBB. The lattercritically contributes to the immune-privileged state of the CNS and secures therestricted passage of substances from the bloodstream into the CNS.Microglia was, aside from epidermal LC [53], the first cells of the innateimmune system that were experimentally proven to be long-lived and independent ofBM-derived myeloid cell replenishment during adulthood [54, 55]. However,compared to LC and other peripheral tissue resident macrophages, murine microgliaexclusively derives from the embryonic yolk sac, without a contribution from fetal liver[56, 57]. This unique feature might have its cause in the BBB that could limit CNS entryof myeloid cells to embryonic yolk sac macrophages. Alternatively, embryonic yolk sacmacrophages might be uniquely able to infiltrate the neuro-ectoderm, due to theirexpression repertoire of matrix metalloproteinases or chemokine receptors [58].In the developing embryonic

CNS, microglia undergoes rapid proliferation and increase incell numbers, but steady state proliferation largely ceases in adulthood [57].Existence of these mechanisms suggests that amicroglia-free brain parenchyma is incompatible with brain function and viability, andthus support the emerging concept that microglia are critical for CNS homeostasis.Microglia is indeed tightly imbedded into the cellular communication with neuroglialcells. Early infiltrating embryonic microglia is highly phagocytic and probably involvedin clearance of cellular debris [58]. Microglia actively engulfs synaptic material andperform synaptic pruning during postnatal development [59-61]. In summary, recent advance in our understanding of microglial biology indicates thatthese cells represent an important component of the CNS, which is imprinted by itsneuroglial surrounding and linked to its unique secluded location behind the BBB.

Splenic Macrophage Populations

The spleen is the largest lymphoid organ in the body and the main site where T and Bcell responses to blood-borne antigens are initiated. Since this organ lacks afferentlymphatics, functions of the spleen are centered on the systemic circulation. The spleenserves as filter of the blood for senescent cells, including erythrocytes, and potentialnoxious materials. Many of the above functions are essentially attributed to specificmacrophage subpopulations that are compartmentalized into different splenic domains,and well adapted to perform site-specific homeostatic roles [62].Red Pulp Macrophages (RPM)are specialized in iron recovery and prominentlyexpress proteins involved in all recycling phases starting from the scavenging ofsenescent or damaged erythrocytes, the uptake of hemoglobin and finally hemebreakdown and iron export [63]. Similarly to KC, RPM also use CD163 for endocytosisof hemoglobin-haptoglobin complexes released from dying erythrocytes [64].

RPM are generated prenatally and maintained throughsteady state adulthood without substantial monocytic input [65, 66]. Of note, the splenic red-pulp is also a site for storageand rapid deployment of monocytes, a potential resource that the body can exploit toregulate inflammation [67].The interface of the splenic white- and red-pulp, called 'marginal zone', is a reticularnetwork and hosts two distinct resident macrophage populations that are strategicallypositioned to screen

entering arterial blood: the marginal zone macrophages (MZM)and the marginal metallophilic macrophages (MMM). As a result of the splenicanatomy, blood flow slows down in the marginal zone and pathogens present in thesystemic circulation are efficiently removed by the macrophage subsets [68, 69].Elimination of MZM and MMM leads toaccumulation of apoptotic cells in the white pulp and their uptake by RPM, resulting inincreased inflammatory cytokine production, enhanced adaptive immunity andaccelerated autoimmunity in disease prone mice [70]. This suggests that MMM andMZM are, as opposed to RPM, specialized in the quiescent removal of their cargo.As for distinct roles of the two cell populations, Marginal Zone Macrophages(MZM) are positioned within the outer layer of the marginal zone and express a unique set of patter recognition receptors (PRR). MZM intimatelyinteract with a specialized non-circulating type of mature B cells that segregateanatomically into the marginal zone.

Marginal Metallophilic Macrophages (MMM) are located adjacent to the white pulpand marginal sinus and form an inner ring of macrophages.Macrophages are also located in the white pulp, which is the site where immuneresponses to blood-borne antigens are initiated and which structurally resembles lymphnodes [68]. **White pulp macrophages** can be identified by their common expressionof the pan macrophage marker CD68. They include 'tingible body macrophages', whichare located in the germinal center (GC) of the B cell follicles. Collectively and in line with the complex architecture and multiple tasks of their organ ofresidence, splenic macrophage subsets display considerable phenotypic and functionalheterogeneity. It remains though unresolved whether these macrophage subsets aredifferent cellular entities with independent ontogeny or alternatively, share precursorsthat are differentially educated in the distinct splenic micro-anatomical niches. Thus, thespleen might represent an excellent model to study site-specific regulatory networks ofdevelopment and / or function.

Conclusion

There are clear examples in which tissue-specific factors drivehighly specialized macrophage functions irrespective of theirontological origin, suggesting tremendous plasticity and redundancyin the mononuclear phagocyte system. Whether embryonicand adult macrophages possess specialized roles has yetto be formally tested. However, our conceptual understandingand genetic tools are now sufficiently developed to preciselyfollow both embryonic and adult macrophage subsets in healthand disease, which should allow important and

unansweredquestions in the field to be addressed. In order todevelop novel therapies, a critical future goal is to harness thisnewfound understanding that different macrophage lineagesexist within tissues and clarify whether these distinct lineagesdifferentially contribute to tissue damage and repair.

Management of Anaphylaxis- A Short Review

Sisira Padavala[1], V. Ashok[2],
Graduate Student[1],Reader[2],Department of Prosthodontics
Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences,Saveetha University, Chennai, India

Abstract

Anaphylaxis is a serious allergic reaction that is rapid in onset and may lead to death.During anesthesia,neuromuscular blocking agents,antibiotics and latex are the most common causes.The rapidness determines its severity.Prompt recognition and management of this condition is imperative.Diagnosis and management are challenging since reactions are often immediate and unexpected.To understand the severity of anaphylaxis and to manage anaphylaxis to determine the risk of death caused by anaphylaxis.

Key Words:*Anaphylaxis,Management,Epinephrine,Allergy, Emergency, Dental office*.

Introduction

Anaphylaxis is an acute, potentially fatal systemic reaction with varied mechanisms and clinical presentations[1,21]. Although prompt recognition and treatment of anaphylaxis are imperative, both patients and healthcare professionals often fail to recognize and diagnose early signs and symptoms of the condition. It is a life-threatening syndrome that requires prompt recognition and treatment.Immediate management includes oxygen administration, epinephrine and i.v fluids[2].Anaphylaxis has a rapid onset with multiple organsystem involvement and is mostly caused by specific antigens in sensitized individuals[3]. It results from the immunologically induced release of mast cell or basophil mediators after exposure to a specific antigen in previously sensitized individuals. Anaphylaxis is a medical emergency that requires immediate attention. Several working definitions of anaphylaxis have been formulated to aid clinical diagnosis and management. Due to differences in recognition, diagnosis and reporting of anaphylactic reactions estimates of lifetime prevalence range between 0.05% and 2%. As with other allergic diseases, several surveys suggest a rising incidence of anaphylaxis[4,5].The most common causes of IgEmediated anaphylaxis are insect, stings,medications,latex,peanuts,tree nuts,fish,milk,eggs,wheat.Idiopathic and exercise induced anaphylaxis also occur[6].In this review, we discuss the current recommendations for its management.All physicians will benefit from knowledge of its recognition and appropriate treatment.

Causes of Anaphylaxis

Most episodes of anaphylaxis are triggered through an immunologic mechanism involving immunoglobulin E (IgE) which leads to mast cell and basophil activation and the subsequent release of inflammatory mediators such as histamine, leukotrienes, tryptase and prostaglandins[7,22].The most common causes of IgE-mediated anaphylaxis are: foods, particularly, peanuts, tree nuts, shellfish and fish, milk, eggs and wheat;medications (most commonly penicillin), and natural rubber latex. Exercise, aspirin, non-steroidal anti-inflammatory drugs (NSAIDs), opiates, and radio contrast agents can also cause anaphylaxis, but anaphylactic reactions to these agents often result from non-IgE-mediated mechanisms.Sometimes it is idiopathic[1,2,27].In children, anaphylaxis is most often caused by foods, while venom-and drug-induced anaphylaxis is more common in adults.

Signs and Symptoms of Anaphylaxis

A wide variety of clinical signs and symptoms involving the skin, gastrointestinal and respiratory tracts and cardiovascular system can be observed.Symptoms have their own onset within minutes but occasionally occur as late as 1 hour after exposure to the offending antigen.The signs and

symptoms may follow a uniphasic course, with resolution of symptoms within hours of treatment, but about 20% of anaphylactic reactions will follow a biphasic course[3].

Table 1: Lists the Symptoms of Anaphylaxis

Table 1	Signs and symptoms
Skin	Urticaria Angioedema Pruritus Erythema Maculopapular rash
Cardiovascular	Tachycardia Hypotension Arrhythmia Syncope Cardiac arrest Dizziness Myocardial infarction
Respiratory ->Upper airway ->Lower airway	Stridor Cough Sneezing Hoarseness Laryngeal edema Nasal congestion Cyanosis Respiratory arrest Tachypnea Accessory muscle use

Table 1	Signs and symptoms
Ocular	Lacrimation Conjunctival injection
Gastrointestinal	Diarrhoea Nausea Vomiting Abdominal pain

Diagnosis

It is not necessary to differentiate between anaphylactic and anaphylactoid reactions at the time of patient presentation since both respond to the same treatment but anaphylactoid shock must be differentiated from other circulatory collapse causes.Anaphylaxis is an unusual, exaggerated allergic reaction. It is mediated by the IgE antibodies and occurs due to re-exposure to an antigen. Anaphylactoid reaction does not involve mediation by the IgE antibodies and occurs without previous exposure to the antigens. The most common conditions that mimic anaphylaxis are vasodepressor reactions characterized by weakness, nausea, bradycardia, pallor, hypotension, vomiting, diaphoresis[1,8,24].Acute respiratory decompensation from severe asthma attacks, pulmonary embolism, foreign body aspiration, myocardial infarction, seizures, acute poisoning can be featured as symptoms suggestive of anaphylaxis but other characteristics like pruritus, urticaria, angioedema are lacking[9].

Management

Anaphylaxis is a medical emergency that may require resuscitation measures such as airway management, supplemental oxygen, large volumes of intravenous fluids, and close monitoring.Administration of epinephrine is the treatment of choice with antihistamines and steroids used as adjuncts[10,25].

Epinephrine

Epinephrine (adrenaline) is the primary treatment for anaphylaxis with no absolute contraindication to its use.The world health organization classifies it as an essential drug.The recommended dose of epinephrine is 0.01mg/kg intramuscular to as much as 0.3mg and it may be repeated within 5 minutes if symptoms worsen or severe symptoms persist[11].The more advanced the anaphylactic reaction, the less likely epinephrine is to reverse the reaction. Epinephrine is life-saving because of its alpha-1 adrenergic vasoconstrictor effects in most body organ systems (skeletal muscle is an important exception) and its ability to prevent and relieve airway obstruction caused by mucosal edema, and to prevent and relieve hypotension and shock[12,13].

Adjuncts

Corticosteroids are unlikely to make a difference in the current episode of anaphylaxis, but may be used in the hope of decreasing the risk of biphasic anaphylaxis[14]. Nebulized salbutamol may be effective for bronchospasm that does not resolve with epinephrine.Methylene blue has been used in those not responsive to other measures due to its presumed effect of relaxing smooth muscle[15].

Treatment

Acute Management

The acute treatment of anaphylaxis begins with rapid assessment of the airway, breathing and circulation. Epinephrine is the drug of choice for anaphylaxis and should be given immediately to any patient with a suspected anaphylactic episode[1].Oxygen therapy should also be considered in any patient with symptoms of anaphylaxis, particularly for those with prolonged reactions. Intravenous fluids should also be provided since massive fluid shifts can occur rapidly in anaphylaxis due to increased vascular permeability[16,17].Vasopressors, such as dopamine, can also be considered if epinephrine injections and volume expansion with intravenous fluids fail to alleviate hypotension[18].If intramuscular epinephrine and intravenous fluids fail to improve anaphylactic symptoms, intravenous infusions of epinephrine may be required.Following acute treatment, patients should be observed for a period of time due to the risk of a biphasicresponseorpossiblerecurrenceofthereactionas epinephrine wears off.

Long Term Management

Assessment

Specialist assessment is a part of longterm management.It helps in assessment of future risk of anaphylaxis for an acute anaphylaxis patient.It helps in analysing causes of anaphylaxis and educating them on proper avoidance strategies, drafting an action plan and advising on immunotherapy[12].

Epinephrine Auto-Injector

Epinephrine auto-injector should be provided to all the patients who have experienced anaphylaxis even those with rapid onset reaction or diffuse hives to insect stings or food.Thereare two kinds of auto-injectors EpiPen and Twinject.They are prescribed according to the weight.0.15 mg for those who weigh between 15-30 kg[1].They should be stored properly and replaced before the expiration date.

Education on Avoidance Measures

Avoidance measures should be considered based on the individual and on age, occupation, activities, personal anxietyand medical care access.

Conclusion

Most of the cases of anaphylaxis are not given timely recognition and remain untreated. This may lead to life-threatening consequences so intramuscular administration of epinephrine is lifesaving.There has to be frequent monitoring of the recovered patients.Recommending management of anaphylaxis in schools and other community settings will help in managing anaphylaxis to a large extent.

Abstract

Opioid pain relieving overdose is avoidable and conceivably deadly condition can comes about because of endorsing hones, insufficient comprehension on the patient's a piece of the dangers of medicine abuse, blunders in sedate organization and pharmaceutical manhandle. There are only few studies being done in the management of opioid analgesic overdose. Normal pharmacokinetic properties are often disrupted during an overdose and can prolong intoxication dramatically. So this review can throw light to the knowledge and management of opioid over dosage. The review is being done for studying the epidemiology of overdose, pathophysiology of opioid analgesics, clinical manifestation, diagnosis and management of over dosage of opioid analgesics.

Keyword*: opioid, overdose, pharmacokinetic, management, pathophysiology, epidemiology*

Introduction

Opioid analgesics overdose is a preventable and possibly deadly condition that outcomes from recommending rehearses, deficient comprehension on the patient's a piece of the dangers of prescription abuse, mistakes in medication organization, and pharmaceutical manhandle which then cannot be taken for granted.[1] Three elements are vital to a comprehension of opioid pain relieving harmfulness.[2] First and foremost, opioid analgesics overdose can have life-undermining harmful impacts in various organ frameworks. Second, ordinary pharmacokinetic properties are regularly upset amid an overdose and can delay intoxication significantly.[3] Third, the term of activity varies among opioid formulations, and inability to perceive such varieties can prompt to wrong treatment choices, at times with lethal outcomes.[4]

Pain is arguably the most common reason why patients seek treatment, especially in the emergency department (ED). The current physician wields many tools to relieve pain, the most potent of which are opioids. The term opiate particularly alludes to any substance that initiates rest, apathy, or trance, and it is utilized to allude to opioids or opioid subsidiaries.The word is derived from the Greek "narke" which means "numbness or torpor." It is common, however inaccurate, that the public uses the term narcotics for any illicit psychoactive substance.

In cultivation since approximately 1500 BC, pure opium is a mixture of alkaloids extracted from the sap of unripened seedpods of Papaver somniferum (poppy). Opiates, such as heroin, codeine, or morphine, are natural derivatives of these alkaloids. The term opiate is often used (albeit slightly incorrectly) to refer to synthetic opiate derivatives, such as oxycodone, as well as true opiates.

Even though opioids constitute a relatively small percentage of total overdoses encountered in the ED, still they merit particular attention because of the potential mortality/morbidity they cause when unrecognized and untreated, as well as the relative ease of reversing their effects. The notable importance of opioids in current prescribing patterns, as well as recreational uses,

mandates that physicians maintain a high index of suspicion when treating the patient who is unconscious for unknown reasons.

Epidemiology of Overdose

The quantity of opioid pain relieving overdoses is corresponding to the quantity of opioid solutions and the measurements prescribed.[5] Between 1997 and 2007, medicines for opioid analgesics in the United States expanded by 7%; the quantity of grams of methadone recommended over a similar period expanded by more than 12%.[6] In 2010, the National Poison Data System, which gets case portrayals from workplaces, doctor's facilities, and crisis offices, announced more than 107,000 exposures to opioid analgesics, which prompted to more than 27,500 admissions to human services facilities.[7] There is impressive cover between psychiatric infection and perpetual torment disorders; patients with depressive or nervousness issue are at expanded hazard for overdose, as contrasted and patients without these conditions, since they will probably get higher dosages of opioids.[8] Such patients are additionally more prone to get calming trancelike specialists (e.g., benzodiazepines) that have been firmly connected with death from opioid overdose.(9) moreover, information demonstrate that the successive remedy of opioid analgesics adds to overdose-related mortality among youngsters, who may discover and ingest operators in the home that were proposed for adults.[10]

Pathophysiology of Opioid Analgesics

Opioids increment action at least one G-protein–coupled transmembrane atoms, known as the mu, delta, and kappa opioid receptors, that create operational differing qualities from join variations, post-translational adjustment and platform of quality items, and the development of receptor heterodimers and homodimers.[11] Opioid receptors are enacted by endogenous peptides and exogenous ligands; morphine is the prototypical compound of the latter.[12] The receptors are generally disseminated all through the human body; those in the foremost and ventrolateral thalamus, the amygdala, and the dorsal-root ganglia intercede nociception.[13] With commitments from dopaminergic neurons, mind stem opioid receptors balance respiratory

reactions to hypercarbia and hypoxemia, and receptors in the Edinger–Westphal core of the oculomotor nerve control pupillary constriction.[14] Opioid agonists tie to receptors in the gastrointestinal tract to reduction gut motility.

The μ-opioid receptor is in charge of the dominance of clinical impacts created by opioids. Considers in knockout mice affirm that agonism of these receptors intercedes both absence of pain and opioid dependence.[15] Furthermore, the improvement of resilience, in which medicate measurements must be raised to accomplish a sought clinical impact, includes the dynamic failure of mu opioid receptors to engender a flag after opioid authoritative. Receptor desensitization, a basic occasion in the improvement of resistance, is a profoundly moderated handle that includes the uncoupling of the receptors from G-protein, and their resulting section into an intracellular compartment amid endocytosis. The receptors may then be come back to the layer in a procedure that resensitizes the cell to opioid authoritative. This dynamic procedure of endocytosis and reusing is hypothesized to constrain the resistance of mu opioid receptors for endogenous opioid ligands as they experience phasic discharge and quick leeway. Conversely, opioid analgesics, which are regulated tediously in long-acting details, hold on in the extracellular grid and flag through mu opioid receptors for delayed periods. Though endogenous local ligands encourage dynamic receptor cycling, opioid analgesics encourage resilience by constantly official and desensitizing the receptors as they limit receptor recycling.[16]

In any case, resistance of the pain relieving and respiratory depressive impacts of opioids is not exclusively identified with the desensitization of mu opioid receptors. Molded resilience creates when patients figure out how to relate the strengthening impact of opioids with ecological signs that dependably foresee tranquilize organization. Opioid use within the sight of these signs has weakened impacts; on the other hand, opioid use without these boosts or in new situations brings about elevated effects.[17]Tolerance of respiratory sadness seems to create at a slower rate than pain relieving resilience; after some time, this postponed resistance contracts the restorative window, incomprehensibly putting patients with a long history of opioid use at expanded hazard for respiratory depression.[18]

Clinical Manifestations of Overdose

The primary clinical appearance of opioid intoxication is respiratory discouragement. Despite the fact that the exemplary toxidrome of apnea, trance, and meiosis recommends the finding of opioid danger, these are not reliably present. Organization of helpful dosages of opioids in people without resilience to opioids causes a perceivable decrease in all periods of respiratory action, with the degree of the decay reliant on the managed dose.[19] At the bedside, in any case, the most effortlessly perceived variation from the norm in instances of opioid overdose is a decrease in respiratory rate finishing in apnea. A respiratory rate of 12 breaths for every moment or less in a patient who is not in physiologic rest emphatically proposes intense opioid inebriation, especially when joined by meiosis or daze. Meiosis alone is inadequate to gather the finding of opioid inebriation. Polysubstance ingestions may create regularly receptive or mydriatic students, as can harming from meperidine, propoxyphene, or tramadol. On the other hand, overdose from antipsychotic drugs, anticonvulsant specialists, ethanol, and other narcotic trancelike operators can bring about meiosis and trance like state, however the respiratory wretchedness that characterizes opioid poisonous quality is typically absent.[20,21]

Disappointment of oxygenation, characterized as an oxygen immersion of under 90% while the patient is breathing encompassing air and with ventilation sufficient to accomplish ordinary blood vessel carbon dioxide strain (halfway weight of carbon dioxide), is frequently created by pneumonic edema that gets to be distinctly obvious later in the clinical course. There are a few potential reasons for aspiratory edema. One likely cause is that endeavored motivation against a shut glottis prompts to a diminishing in intrathoracic weight, which causes liquid extravasation. Then again, intense lung damage may emerge from a component like that hypothesized for neurogenic aspiratory edema. In this situation, thoughtful vasoactive reactions to worry in a patient who has stirred after inversion of inebriation finish in spillage from aspiratory capillaries.[22]

Hypothermia may emerge from a tirelessly inert state in a cool domain or from confused endeavors by observers to turn around opioid inebriation by inundating a patient in icy water. What's more, people who have been lying stationary in an opioid-initiated daze might be liable to rhabdomyolysis, myoglobin uric renal disappointment, and the compartment disorder. Other lab variations from the norm incorporate lifted serum aminotransferase fixations in relationship with liver harm created by acetaminophen or hypoxemia. Seizures have been related with overdose of tramadol, propoxyphene, and meperidine.[23,24]

Symptoms

The symptoms for opiate poisoning may be a chronic problem, in which case the main complaint will be of constipation. There may be nausea, vomiting or just loss of appetite. There may be sedation and craving for the next dose. Moreover, acute toxicity presents with drowsiness that will be more severe if there is also alcohol involved, or involvement of other sedatives. There may be nausea or vomiting.

Signs [25]

One of the signs is respiratory depression may be apparent. Hypotension and tachycardia are possible. There are usually pinpoint pupils but this sign may be absent if other drugs are involved. Besides, the 'post-mortem sole incision' sign has been identified. This is an incision made in the sole by an acquaintance in the belief that the subsequent blood loss will reduce the likelihood of death in an individual who has taken an accidental overdose of an opiate.

Diagnosis of Overdose

The nearness of hypopnea or apnea, meiosis, and daze ought to lead the clinician to consider the finding of opioid pain relieving overdose, which might be construed from the patient's indispensable signs, history, and physical examination. In patients with extreme respiratory

misery, rebuilding of ventilation and oxygenation outweighs getting the historical backdrop of the present disease or playing out a physical examination or demonstrative testing.

After the patient's condition is balanced out, the clinician ought to ask about the utilization of all opioid analgesics, acetaminophen (counting items coformulated with acetaminophen), and illegal substances and figure out if the patient has had contact with anybody accepting pharmacologic treatment for constant torment or opioid dependence.[26] In playing out the physical examination, the clinician ought to assess the size and reactivity of the understudies and the level of respiratory exertion and search for auscultatory discoveries suggestive of pneumonic edema. The patient ought to be totally uncovered to take into consideration a careful look for fentanyl patches. Also, the clinician ought to palpate muscle assembles; the solidness, swelling, and delicacy that describe the compartment disorder (which comes about when lethargic patients lie on a muscle compartment for quite a while) warrant coordinate estimation of compartment weights. At last, the acetaminophen focus ought to be measured in all patients in light of the commonness of redirection and abuse of acetaminophen-containing opioids. Clinicians regularly ignore acetaminophen hepatotoxicity.[27]

Subjective examinations of pee for medications of manhandle (toxicology screens) once in a while influence choices about patient care and have little part in the quick assessment and administration of opioid inebriation, for a few reasons. To begin with, naloxone ought to never be withheld from a patient with apnea on the grounds that the consequences of subjective tests are inaccessible. Second, the administration of opioid overdose, regardless of the causative operator, changes nearly nothing. At last, standard poisonous screens, which recognize methadone, fentanyl, hydromorphone, and different mixes just occasionally, give minimal valuable clinical data. More current subjective screens that distinguish a more extensive scope of opioid analgesics may permit clinicians spend significant time in torment treatment, psychological well-being, or different territories of pharmaceutical to recognize patients who have strayed from recommended treatment regimens; more prominent diagnostic exactness, notwithstanding, does not change the administration of intense overdose. Quantitative measures

of medication fixations are futile in instances of overdose in light of the fact that patients who have been recommended raised dosages of opioid analgesics may have helpful serum focuses that enormously surpass research facility reference ranges.[38]

Management

- Do not postpone building up an unmistakable aviation route, satisfactory ventilation and oxygenation if awareness is impaired.[29]
- Give naloxone intravenously (IV) (0.4-2 mg for a grown-up and 0.01 mg/kg body weight for kids) if trance like state or respiratory misery is present.
- Give intramuscularly (IM) if no vein is accessible. Rehash the measurement if there is no reaction inside two minutes. Naloxone is an aggressive rival and huge measurements (4 mg) might be required in a seriously harmed persistent.
- Failure of an unmistakable sedative overdose to react to vast measurements of naloxone proposes that another focal sensory system (CNS) depressant, or cerebrum harm, is available.
- Observe the patient precisely for repeat of CNS and respiratory dejection. The plasma half-existence of naloxone is shorter than that of all opioid analgesics. Rehashed measurements might be required. Naloxone IM ought to be considered if the patient is debilitating to self-release, as it might help decrease the danger of respiratory capture when the IV naloxone wears off.
- If somebody takes an overdose of IV heroin it is critical to regulate naloxone at the earliest opportunity. Frequently this is finished by paramedics however a few people have pushed that clients ought to have a supply on the off chance that one of their number overdoses and treatment can be begun immediately. They are frequently hesitant to call for help.[30]
- IV mixtures of naloxone might be helpful where rehashed measurements are required. Naloxone 400 micrograms/ml is weakened with sodium chloride 0.9 % or glucose 5%.

Five ampoules of naloxone 400 micrograms/ml (2 mg) per 500 ml give 4 µg/ml. 66% of the bolus measurement expected to turn around inebriation given hourly as a consistent implantation regularly keeps up respiratory exertion without advancing sedative withdrawal. Implantations are not a substitute for continuous audit of the patient's clinical state.

- Give oral actuated charcoal, gave the aviation route can be ensured, if a generous sum has been ingested inside two hours.
- Naltrexone is prescribed by the National Institute for Health and Care Excellence (NICE) as a treatment choice for individuals who have been opioid-subordinate however who have quit utilizing opioids and who are exceptionally energetic to remain free from the medications in a restraint program. It is an aggressive sedative enemy that will hinder the impact of heroin. It ought to just be given to individuals who have been told about the issues related with treatment and with legitimate supervision. Treatment with naltrexone ought to be given as a major aspect of a bolster program to help the individual deal with their opioid dependence.[32]
- Choices incorporate vigilant holding up, with or without the utilization of intestinal medicines, entire entrails water system, endoscopic expulsion or surgery. A hazard advantage examination ought to be performed, mulling over whether the patient is symptomatic or asymptomatic and whether the treatment is probably going to increment or abatement the danger of bundle crack. Most patients can be overseen by careful holding up and released from doctor's facility when the bundle has been emptied with an ordinary solid discharge. Surgery ought to just be performed in body packers with indications of inebriation or ileus.[33]
- A new naloxone auto-injection device to treat opioid overdose.[34][35]

Summary

Opioid pain relieving overdose is an existence due to certain chronic cases that require opioid analgesics as the medication. Thus, since there is a lot of consuming opioid analgesics, this situation will lead to over dosage of opioid analgesics.[36] Therefore, medical experts have to look on this condition better because the effects of opioid analgesics overdose are too severe. Moreover, opioid analgesic poisoning is a life-threatening condition, and the antidote which is naloxone may have limited effectiveness in patients with opioid poisoning due to over dosage. [37]This unpredictable clinical course of intoxication requires empirical management of this potentially lethal condition so that it would not cause any troubles in future.[38][39]

Abstract

Anticoagulation therapy is one of the most prevalent forms of treatment used in contemporary medicine. Thrombogenesis (clot formation) includes 2 principal processes: platelet aggregation and coagulation. The aim of this literature review is to evaluate the available evidence on the impact of anticoagulant medications on dental treatment and highlight certain patient management issues closely interrelated to various aspects of dental treatmentImpact of anticoagulants on patients undergoing dental treatment is very high.Mainly for cardiac patients, the physician's consent is mandatory before undergoing any dental procedures.INR value plays a major role play here which is now widely used for monitoring anticoagulant therapy and dosage planning.

Key Words*: platelet, coagulation, dental, anti-coagulant, thrombosis, fatal*.

Introduction

Millions of patients worldwide take medications that alter hemostasis in order to reduce the risk for thromboembolic events, such as strokes. Anticoagulation therapy is one of the most prevalent forms of treatment used in contemporary medicine. Thrombogenesis (clot formation) includes 2 principal processes: platelet aggregation and coagulation. These patients, however, present the most common potential bleeding problem that dentist's encounter.Oral anticoagulant therapy is prescribed for both prophylactic and therapeutic purposes.[1]Oral Anticoagulants reduce blood clotting which can help prevent deep vein thrombosis, pulmonary embolism, myocardial infarction and ischemic stroke. Frequently raised questions concern the safety and efficacy of the various anticoagulation regimens and their accompanying thromboembolic and bleeding risks relative to invasive dental procedures. The aim of this literature review is to evaluate the available evidence on the impact of anticoagulant medications on dental treatment and highlight certain patient management issues closely interrelated to various aspects of dental treatment.

A 2006 survey of hematologists and dentists revealed no consistent management of preoperative anticoagulation. Preoperative management ranged from the continuation of the regular dose of anticoagulant to reduction of the dose to its complete cessation. Another practice is to stop warfarin 5 days before the procedure and administer bridging anticoagulation, typically low-molecular-weight heparin, for patients at high risk of thromboembolism. This approach, which aims to avoid a residual anticoagulant effect at the time of the procedure, deals with dentists' perception of an increased risk of serious bleeding if warfarin is not interrupted. Dentists' concern about post-operative bleeding may be based, in part, on their observation that for patients not on anticoagulation, bleeding after dental procedures, such as extractions, can be excessive, given the highly vascular supporting structures. Prevention of oral bleeding is also desirable because it can be distressing for patients, presents challenges for the homebound elderly and may deter future dental care. Interruption of warfarin therapy, however, may increase the risk of thromboembolism, such as stroke, which can be associated with mortality and long-term morbidity.Further, bleeding after dental surgery is easily seen and usually self-limiting, and most often can be managed with local measures, such as biting on gauze. [2]

Finally, recent editorials and review shave suggested that dentists concerns about the risk of bleeding when procedures are done on patients taking anticoagulation havebeenover stated against this background, we did a systematic review of studies assessing outcomes for patients treated with anticoagulants who required elective dental procedures. We aimed to determine the risk of-bleeding for patients who continued warfarin therapy compared with that for those whose dose was reduced or interrupted.

Oral Anti Coagulation Medication

The most frequently used medications for oral anticoagulant therapy are: Anticoagulants with indirect action (coumarin derivatives)

a. Acenocoumarol- derivative of coumarin and vitamin K antagonist.

b. Warfarin sodium- it is also a derivative of coumarin.

c. Phenindione

The novel oral anticoagulants [NOACs] or directly acting oral anticoagulants [DOACs] are:

Direct Thrombin Inhibitors

a. Dabigatran- is a selective, reversible direct inhibitor.

b. Argatroban

Direct Factor XaInhibitors

a. Apixaban- is a potent, reversible, highly selective direct inhibitor.

b. Rivaroxaban

c. Edoxaban

Test for Anti Coagulation Assessment

The prothrombin time ratio (PTR), defined as the patient's prothrombin time (PT) was used to monitor anticoagulant therapy for many years. Because of the variability of Prothrombin Time (PT) values from different reagents, a system of standardizing the reporting of anticoagulation activity has been developed by the World Health Organization. In 1985, the International Committee on Thrombosis and Homeostasis requested that all lots of thromboplastin have an indication of their international sensitivity index (ISI) which allows standardization of the results from different laboratories by the introduction of the INR. [3,4]

INR = [PT test / PT normal]

INR- International Normalized Ratio

It is now widely used for monitoring anticoagulant therapy and dosage planning. The INR for a healthy patient is 1 and the therapeutic INR for those on anticoagulant therapy typically ranges from 2 to 4, depending on the reason for anticoagulation.

Risk of Thrombosis on Stopping Anti-Coagulants

In the past decade, it has become clear that routine discontinuation of oral anticoagulant therapy for dental procedures is not supported by the scientific literature, as it may put patients at unnecessary medical risk for thromboembolic events either from the cessation of anticoagulant therapy or because of rebound phenomenon unless serious bleeding is anticipated, the therapy should be continued.The risk of thrombosis associated with temporarily discontinuing anticoagulants prior to dental surgery is small but potentially fatal. Currently, most guidelines indicate that patients with an INR less than 3.5 can undergo minor oral surgery (e.g., simple single extraction) without any adjustment in anticoagulation. Withdrawal or temporary interruption of anticoagulant medication, could lead to thromboembolic events.[5]

Risk of Bleeding on Continuing Anti-Coagulants

The gums and their supporting structures are highly vascular and prone to bleeding when damaged. While visible bleeding in the mouth is not considered as dangerous as "silent" bleeding that occurs internally or at non-compressible sites, oral bleeding can be distressing for the patient and potentially life threatening. However, many primary care dental procedures are unlikely to cause bleeding that cannot be managed with local measures. These include minimally invasive procedures such as periodontal probing, scaling above the gum like, polishing, and orthodontic procedures. Invasive procedures such as local infiltration, scaling below the gums, root planning, biopsies, tooth extractions, minor periodontal surgery, cavity filling, endodontic procedures (root canals), and prosthodontic procedures (crowns, bridges, and implants) are also unlikely to cause

significant bleeding. Significant bleeding is more likely to occur with more invasive procedures such as extraction of impacted teeth and use of periodontal flaps.[6,7]

Patients with liver disease, kidney disease, hypertension, and gingival disease also have an increased risk of bleeding. The skill and experience of the dental practitioner and availability of haemostatic measures must also be considered when deciding whether to stop anticoagulants or anti-platelet agents.One of the most frequently cited studies regarding thromboembolic risks in dentistry are Wahl's literature review in which 5/493 patients who stopped anticoagulants for a dental procedure had serious embolic complications, including 4 deaths. This report has been criticized because the patients had stopped anticoagulation for longer than usually recommended and the relationship to coagulation status was unclear. However, considering that recurrent venous thromboembolism is fatal in ~6% of patients and arterial thromboembolism is fatal in ~20%, many consider the risks of thromboembolism outweigh the risks from bleeding from oral procedures.Thromboembolic risks vary with the reason for anticoagulation or anti-platelet therapy. The American College of Chest Physicians has published a stratification of thromboemobolicrisk.Dabigatran and rivaroxaban are not included, but risks would likely be similar to warfarin for similar indications.

The authors concluded that the risk of thromboembolism outweighed the risk of postoperative bleeding and patients whose INR is up to 4.0 do not have clinically significant bleeding post-operatively. The risks of bleeding that occurs in patients on continued anticoagulant therapy after dental surgical procedures can be easily controlled by local homeostatic measures.

Local Measures Used in Bleeding Control

Local Homeostasis

Local homeostasis after single or multiple teeth extractions can be achieved through: - Local pressure (biting on gauze); site packing with gelatin sponges; absorbable oxy cellulose; microcrystalline; collagen; additional suturing; Electro cauterization; topical thrombin powder.

Fibrin sealants induce clot formation at the site of the surgical wound. It mimics the last phase of blood clotting by conversion of fibrinogen to fibrin. The system has 2 components. The first consists mainly of fibrinogen and plasma proteins, and the second consists of thrombin and calcium chloride. When the 2 components are mixed, thrombin converts fibrinogen into fibrin so

that clotting is initiated and the mixture is solidified. Fibrin sealants for oral surgery in patients on oral anticoagulant therapy can be used to reduce postoperative hemorrhage in the therapeutic INR range of 1 to 5 in patients with a wide range of degrees of surgical trauma. 5% tranexamic acid mouthwashes used 4 times a day for 2 days (10ml in mouth for 2min) was reported to be effective in patients on anticoagulant therapy. This treatment modality is an attempt to reduce the amount of lysed fibrin and consequently the incidence of postoperative bleeding. It is conceivable that the mouthwash may have an effect only on the superficial clot and not on bleeding from the depth of the socket, an area not accessible to the mouthwash. [8]

Pain Control

Generally paracetamol is considered a safe analgesicdrug for patients taking anticoagulant medications and it maybe taken in normal doses if pain control is needed and no contraindicationexists.Recommendations of the British Committee for Standards in Hematology. Patients taking warfarin shouldnotbe prescribed nonselective NSAIDs as analgesicsfollowing dental surgery. These drugs inhibit platelet aggregation and may cause GI bleeding and peptic ulceration and/or perforation. Increased bleeding may occur during concomitant NSAID therapy with warfarin independently of an increase in INR.Patients taking Acenocoumarol should not be prescribed nonselective NSAIDs as analgesics following dental surgery, which potentate bleeding.

Association of new oral anticoagulants with other anticoagulants, platelet inhibitors(Aspirin, Clopidogrel, Ticlodipine, Prasugrel,Ticagrelor, and others), and non-steroidal anti-inflammatory drugs (NSAID) increases the bleeding risk. COX-2 inhibitors are unlikely to increase bleeding time following invasive dental procedures, although thereare no prospective studies in humans.Interactions with drugs frequently used or prescribed in dentistry.Macrolide antibiotics (i.e., erythromycin, clarithro-mycin, and possibly azithromycin) and sulphonamides havebeen implicated in causing significant episodes of bleedingin patients taking warfarin or acenocoumarol. Other drugs that may enhance the hypoprothrom-binemic effect of anticoagulant drugs include tetracyclines(especially doxycycline or tetracycline), and in particular the second and third generation cephalosporins, andlevofloxacin.Postulated mechanisms include an antibiotic-induced reduction in prothrombin activity(hypoprothrom-binemic) and a reduction in

gastrointestinal bacteria flora essential for vitamin K production which is subsequently used to produce various clotting factor.Dabigatran and rivaroxaban are reported to have comparatively few drug-drug interactions.The concomitant use of systemic azoleantimycotics(ketoconazole, Iitraconazole, voriconazole, andposaconazole) as well as HIV protease inhibitors is not recommended in patients being treated with rivaroxaban.Fluconazole is expected to have less effect on rivaroxaban exposure and can be co-administered withcaution.Although platelet aggregation was reported to beunaffected, concomitant use of some NSAIDs and rivaroxaban significantly increased bleeding time comparedwith rivaroxaban alone. [9,10]

Interaction with Drugs Frequently used in Dentistry

Macrolide antibiotics (i.e., erythromycin, clarithromycin, and possibly azithromycin) and sulphonamides have been implicated in causing significant episodes of bleeding in patients taking warfarin or acenocoumarol. Other drugs that may enhance the hypoprothrom- binemic effect of anticoagulant drugs include tetracyclines (especially doxycycline or tetracycline), and in particular the second and third generation cephalosporins, and levofloxacin. Postulated mechanisms include an antibiotic- induced reduction in prothrombin activity (hypoprothrombinemia) and a reduction in gastrointestinal bacteria flora essential for vitamin K production which is subsequently used to produce various clotting factors.Dabigatran and rivaroxaban are reported to have comparatively few drug-drug interactions. [11]The concomitant use of systemic azoleantimycotics (ketoconazole, itraconazole, voriconazole, and posaconazole) as well as HIV protease inhibitors is not recommended in patients being treated with rivaroxaban.

Fluconazole is expected to have less effect on rivaroxaban exposure and can be coadministered with caution. Although platelet aggregation was reported to be unaffected, concomitant use of some NSAIDs and rivaroxaban significantly increased bleeding time compared with rivaroxaban alone. There are potential weaknesses of our systematic re-view. First, we searched only the English-language literature. However, the degree of bias introduced by the exclusion of non-English literature is debatable. A study of number of disease areas showed that language-restricted meta-analyses, compared with language-inclusive meta-analyses, did not differ in their estimate-of the benefit or the effectiveness of an intervention.

Second, in our meta-analysis, 4 of 5 trials were of low methodological quality, scoring only 1 or 2 on a validated quality assessment scale. Only 1 study included a description of withdrawals and dropouts.Two19,21of the 5 trials did not report the indication forwarfarin therapy for their patient population, which determines the therapeutic range of the INR at which patients are normally maintained and gives a sense of the risk of bleeding and thromboembolism. Studies that include a majority of patients anticoagulated for atrial fibrillation or native valvulopathy maintained at lowerINRs (2.0–3.0) would be expected to show a lower incidence of bleeding than studies that include patients on anticoagulant therapy who have prosthetic heart valves and are therapeutically maintained at higher INRs (2.5–3.5). In addition to INR, surgical skill, complexity of thesurgical procedure, comorbid conditions such as liverdisease or blood dyscrasias, and the effect of combined therapy with antiplatelet and nonsteroidal anti-inflammatory agents can increase the risk of bleeding during a surgical procedure. Further, 5 studies included in this systematic review were conducted in a hospital setting. In 1 study,20th setting was not specified. It is possible that the results from this review maynot be generalizable to private practice.[12,13]

Our findings question the current practice of interrupting warfarin therapy for dental procedures. However, a number of pragmatic questions from everyday dental practice preclude an across-the-board recommendation continuewarfarin therapy around the time of dental procedures. For example, questions arise about management of patients with comorbid factors; the use of additional local measures and antifibrinolytic agents; and the need for referral to specialists, hospital care, or bridging therapy. Nonetheless, this is a clinical dilemma that is too prevalent and too important to defer because of insufficient evidence, with resulting continued ambiguous.

Summary

Dental treatment performed in patients receiving oral anticoagulant drug therapy is becoming increasinglycommon in dental offices.The aim of oral anticoagulant therapy is to reduce blood coagulability to an optimal therapeutic range withinwhich the patient is provided some degree of protection fromthromboembolic events. This is achieved at the cost of a minor risk of hemorrhage.Frequently raised questions concern the safety and efficacy of the various

anticoagulation regimens and their accompanying thromboembolic and bleeding risks relative to invasive dental procedures.

The aim of this literature review is to evaluate the available evidence on the impact of anticoagulant medications on dental treatment and highlight certain patient management issues closely interrelated to various aspects of dental treatment.For that purpose literature search in the electronic database of Medscape, PubMed-Medline, Science Direct, and EBSCO host, in the data base of Medical UniversityPlovdiv and specialized published books in general medicineand dentistry was made. A total of 33 publications between 1995 and 2013were identified: 12 review articles, 11 randomized controlledandnon-randomized studies, 6 guidelines and practicalguides, 1 meta-analysis and 3 specializedbooks.[14,15]

Conclusion

INR values should be obtained within 24 hours before the dental procedure. For patients with INR in the therapeutic range 2-4 or below, therapy need not be modified or discontinued for simple single dental extractions. More complicated and invasive oral surgical procedures for patients with an INR on the high end of the scale or greater than 3.5 should be referred to physician for dose adjustment or therapy alteration before invasive dental procedures. The risk of bleeding may be minimized by: use of oxidized cellulose or collagen sponges, fibrin sealants.[15]

Tranexamic acid mouthwashes used four times a day for 2days.Co morbid conditions as liver disease, bone marrow disorders, biliary tract obstruction, malabsorption, renal disease, and cancers such as leukemia may potentate anexisting bleeding problem. Increased inflammation of theoral tissues in patients on OAT can contribute to excessive bleeding even with minor procedures.These patients should NOT have a surgical dental procedure and should be referred to a dental hospital or hospital-based oral and maxillofacial surgery department.[16,17]

The use of concomitant medications, including antibiotics, antifungals, non-steroidal anti-inflammatory drugs(NSAIDs), and other platelet aggregation inhibitors may affect a patient’s ability after a routine dental procedure. For patients being treated with one of these new oral anticoagulants, the amount of “real-world” data and experience regarding the management of

patients undergoing dental procedures that are likely to involve significant bleeding is currentlylacking.Clearly, clinical studies are needed to determine the effects that the new oral DTIs and FXaIs have on bleeding and hemostasis after tooth extractions and other surgical and dentalprocedures. At this time patients taking dabigatran, rivaroxaban,orapixaban should be consulted with the treating physician prior dental surgical procedures.[18,19]

The aim of oral anticoagulant therapy is to reduce blood coagulability to an optimal therapeutic range within which the patient is provided some degree of protection from thromboembolic events.Impact of anticoagulants on patients undergoing dental treatment is very high.Mainly for cardiac patients, the physician's consent is mandatory before undergoing any dental procedures.INR value plays a major role play here which is now widely used for monitoring anticoagulant therapy and dosage planning.[20,21,22]

Maxillary Sinus- A Review of Literature

SameerMohideenGani[1], AravindSivakumar[2],

Graduate Student[1], Senior Lecturer[2], Department of Orthodontics,

Saveetha Dental College, Saveetha Institute of Medical and Technical Sciences, Saveetha University, Chennai, India

Abstarct

The maxillary sinuses are a subset of the paranasal sinuses and can generally be thought of as the sinuses, or cavities, beneath the cheeks and on the sides of the nose. The maxillary sinuses are the most common region that paranasalsinus cancer arises, and most cancers in the maxillary sinuses are squamous cell carcinomas, meaning they arise from flat, thin cells in the epidermis lining the maxillary sinus. Malignant tumors of the paranasal sinus are uncommon, constituting less than 1% of all malignancies and 3% of all head and neck cancers. Nonsquamous cancers of the maxillary sinus are even rarer as is evident from the limited data available on the clinical characteristics and outcomes. Mucoepidermoid carcinoma accounts for 13% of all malignancies occurring in maxillary sinus.

Key Words: *Maxillary sinus, IA, CCRT, Carcinoma, Malignant neoplasm*

Introduction

Oral squamous cell carcinoma represents 90% to 95% of all malignant cancers of the oral cavity. It is classically regarded as an adult disease and has a high correlation with alcohol and tobacco consumption. Oral Squamous cell carcinoma occurs in several well established intraoral sites, including the floor of mouth, tongue (most common), gingiva, lips, and buccal mucosa. It might also present in the tooth-bearing segment of either the maxilla or the mandible, with bony involvement. The standard treatment in the early stage of maxillary sinus cancer is surgical resection followed by radiation therapy.

Computed and frontal tomograms were taken of 20 patients with carcinoma of maxillary sinus and were evaluated in order to compare the diagnostic accuracy of both the procedures. The diagnostic accuracy of CT in diagnosing the tumor was was greater than frontal tomography.

Maxillary Sinus

Malignant neoplasms of the paranasal sinuses and nasal cavities are rare ,comprising only 3% of all head and neck malignancies. Malignancies of the nasal cavity and paranasal sinuses constitute fewer than 1% of all malignancies and 3% of upper aerodigestive tract malignancies.[1] The majority of these tumors are in the maxillary sinus, and squamous cell carcinoma is the commonest histological type.[2] As a subset of maxillary sinus malignancies, non-squamous cell cancers of the maxillary sinus are rare .[3] Sinonasal malignancies occur twice as often in males as in females, and are most often diagnosed in patients 50 to 70 years of age.[4] Mucoepidermoid carcinoma arising from mucous glands of maxillary sinus are extremely rare and accounts for 13% of all malignancies occurring in maxillary sinus.[1]

Sinus means “pocket” in Latin. Humans have these air-filled spaces that surround the nasal cavity called paranasal sinuses. The four-paired paranasal sinuses include frontal and ethmoid sinuses between the eyes, sphenoid sinuses behind the ethmoid, and maxillary sinuses surrounding the nasal cavity. The maxillary sinuses are the largest of the paranasal sinuses. Although not proven, the biological roles of sinuses include decreasing the relative weight of skull, increasing voice resonance, providing a buffer against blows to face, insulating structures, and humidifying/heating inhaled air. (12)

The maxillary sinus is pyramidal in shape. The base of the pyramid is the medial wall of the sinus that is also the lateral wall of the nasal cavity, and its apex is pointed toward the zygomatic bone. The roof of the sinus is also the floor of the orbit. The average volume of a sinus is about 15 ml (range between 4.5 and 35.2 ml). The maxillary sinus maintains its overall size while the posterior teeth remain in function as the size expands with age, especially when posterior teeth are lost. This process is called pneumatization and is possibly the result of atrophy caused by reduced strain from occlusal function.

The membrane that lines the walls of the maxillary sinus is called Schneiderian membrane. It is multilayered and 0.13 mm to 0.5 mm in thickness. The layers include the respiratory epithelium

(pseudo-stratified ciliated columnar epithelium) that covers a loose, highly vascular connective tissue and periosteum. The healthy maxillary sinus is self-maintaining by postural drainage and actions of the ciliated epithelial lining, which propels bacteria toward the ostium. The ostium is a nonphysiologic drainage port high on the medial wall that opens into the nasal cavity between the middle and lower nasal conchae (hiatus semilunaris).

At its highest point, the ostium is located 30 mm above the floor and serves as an anatomic rationale for the sinus floor elevation procedure. Sinus elevation may improve the symptoms of sinusitis and congestion by bringing the floor of sinus closer to the drainage port, and the grafting procedure does not interfere with normal sinus function. (12)

The blood supply to the maxillary sinus is derived primarily from the maxillary artery. The posterior superior alveolar and infraorbital arteries anastomose in the bony lateral wall. (13) On average, the intraosseous anastomose (IA) occurs in 100% of the cases and 19 mm from the alveolar bone crest, whereas the extraosseous anastomose (EA) occurs in about 40% of the cases and 23 mm from the alveolar bone crest. There may be one or more septa dividing the maxillary sinuses, called Underwood's septa. (14,15,16) It occurs about 30% of the time and in the anterior region (most commonly between the second premolar and first molar) about 77% of the time. The mean height of the septae is 7.9 mm (range 0 to 17 mm). (14,15,16)

As mentioned above, the maxillary sinus provides a challenge in implant dentistry because of the reduced bone volume, which is due to alveolar bone resorption and pneumatization of the sinus cavity. Several ways to avoid the sinus cavity is to use a short implant, tilt the implant mesially or distally, use a long zygomatic implant, and/or shorten the dental arch with premolar occlusion. With the premolar occlusion, 50% to 80% of chewing capacity is maintained. (17) However, over the years, techniques have been developed to augment the sinus floor.

Philip Boyne is the first to report the elevation of the maxillary sinus floor for preprosthetic reasons. The maxillary sinus was augmented prior to a tuberosity reduction to increase the interarch distance and create a more symmetric maxillary arch for denture prosthesis. (18) Boyne also reported on the two-stage elevation of the maxillary sinus floor as a preparation for the placement of blade implants. He grafted the maxillary sinus with autogenous particulate iliac bone, and then placed blade implants three months later. (19)

Hilt Tatum suggested the crestal approach for sinus floor elevation with subsequent implant placement. A “socket former” was used to prepare the implant site and create green-stick fracture of the sinus floor. A root-formed implant was placed and allowed to heal in a submerged way. (20)

Robert Summers described another crestal approach — BAOSFE (Bone-Added Osteotome Sinus Floor Elevation) — using tapered osteotomes with increasing diameters. Adjacent bone was compressed by pushing and tapping as the sinus membrane was elevated. Autogeneous, allogenic, or xenogenic bone grafts were added to increase the volume below the elevated sinus membrane. Using this approach, Summers reported a 96% success rate at 18 months after loading 173 press-fit submerged implants. (21)

There are two major approaches to elevate the sinus floor: lateral window and transalveolar approach. The lateral window approach can be one- or two-stage techniques for implant placement; the transalveolar approach is a one-stage technique, mainly based on available residual bone and the possibility of achieving the primary stability of the implant.

Risk Factors

People who are exposed to mustard gas, isopropyl oils, volatile hydrocarbons, or metals like nickel and chromium (which occurs most commonly in the leather tanning, nickel mining and carpentry industries) have an increased risk of developing paranasal cancer including maxillary sinus cancer.

Furthermore, past exposure to an extremely long-acting radioactive chemical called Thorotrast that was used for radiographic studies in the 1960s is thought to increase the risk of maxillary sinus cancer. Chronic sinusitis may also increase the risk of developing the disease.

In addition, tobacco use increases the risk of developing the most common form of maxillary sinus cancer (squamous cell carcinoma) although tobacco's role in other types of paranasal and maxillary sinus cancer is less clear.

Discussion

Oral SCC is a disease entity with well established risk factors, including smoking and alcohol use. It can present on the tongue (most common), floor of the mouth, buccal mucosa, or gingiva and commonly presents as a nonhealing, exophytic or endophytic ulcer with associated local and regional pain. Otalgia, dysphagia, mobile teeth, and weight loss might also be present.

Oral SCC is typically associated with the mandible or the maxilla but will slowly invade the underlying tissues after onset. Invasive maxillary SCC will exhibit a multitude of clinical signs and symptoms, which might mimic facial pain syndromes, including . In the early stages of the disease, the patient will first complain of localized maxillary pain; later, symptoms might progress to mobility of teeth. This was noted in the discussed case. As the tumour invades the maxilla and infiltrates the maxillary sinus, the patient will experience nasal congestion due to direct-obstruction symptoms. The infraorbital nerve (branch of the maxillary division of the trigeminal nerve) will also be affected, resulting in sensory disturbances of the cheek.

Maxillary sinus carcinoma presents a therapeutic challenge to both the surgeon and the radiation oncologist. Because symptoms are vague and nonspecific, the majority of carcinomas are diagnosed as locally advanced disease [5]. Extension to contiguous structures including the orbit, ethmoid sinus, sphenoid sinus, nasal cavity, nasopharynx, pterygoid fossa, palate and cheek may occur and can be a potential problem in the surgical and/or radiotherapeutic management of this disease [5, 6]

Maxillary sinus malignancies are very difficult tumors to treat and traditionally have been associated with a poor prognosis. One reason for these poor outcomes is the close anatomic proximity of the nasal cavity and paranasal sinuses to vital structures such as the skull base, brain, orbit, and carotid artery.[7] This complex location makes complete surgical resection of sinonasal tumors a challenging and sometimes impossible task. In addition, mucoepidermoidcarcinoma of maxillary sinus tend to be asymptomatic at early stages, appearing more frequently at late stages once extensive local invasion has occurred.

The unfortunate combination of complex surrounding anatomy with late, advanced stage presentation leads to the frequent local recurrence and subsequent poor outcome associated with sinonasal malignancies. Overall 5-year survival for maxillary sinus MEC is 36%.[8] The early diagnosis is critical for better prognosis of this tumor. So also it suggests that MEC of maxillary sinus should be considered in the differential diagnosis of swellings in maxilla. The prognosis of maxillary sinus cancer is disappointing, despite aggressive treatments. For successful treatment outcomes, it is necessary to acquire complete surgical resection and to secure adequate resection margins.

However, maxillary sinus cancers usually are diagnosed at advanced stages, and the proximity of important organs such as the eyes and cranial nerves makes complete surgical resection difficult. In addition, functional impairments after surgical resection are the major cause of a decreased quality of life. Therefore, surgical resection with a curative intent should be considered as a primary treatment only in the early stages of the disease. In the advanced stages, multimodality treatment strategies should be arranged for prolongation of survival and improvement in the quality of life.

Maxillary sinuses can vary in size and shape from one individual to another, or even between the right and left sides in the same individual. In approximately half of the population, their length also varies. The floor of the maxillary sinus extends into the alveolar process between the roots of adjacent teeth, creating elevations and depressions called "extensions," with narrow cortical areas.(22) Through histological sections, it has been radiographically demonstrated that most of the roots projecting into the maxillary sinus were in fact surrounded by a thin layer of cortical bone, with perforations present in 14-28% of cases. (23) Under normal conditions, the relationship between the tooth and the floor of the maxillary sinus consists of either a thin layer of compact bone that provides support to the apical periodontal ligament fibers, to which it firmly adheres, or there is a direct relationship with the maxillary sinus mucosa. The inner lining of the maxillary sinus cavity is devoid of periosteum; therefore, in the absence of a thin layer of intervening bone, the periodontal tissues are in direct contact with the basal surface of the sinus mucosa. (24)

The roots of the upper premolars, molars, and occasionally the canine teeth have a close relationship with the maxillary sinus; in some cases, they may even protrude into it.(24,25,26). It has been demonstrated that the closer the tooth apex is to the floor of the maxillary sinus, the greater the impact on antral tissue. (27) This relationship can result in a variety of risks, especially for certain surgical procedures, such as tooth extraction and implant placement, or during endodontic or orthodontic treatments.(28) An accurate description of the relationship between the apices of the upper teeth and the lower wall of the maxillary sinus, as well as the thickness of the cortical bone between these structures, is essential for planning dental procedures.

Dental radiographs, such as panoramic radiography, consist of two-dimensional images and, as such, are inappropriate and/or of little use for accurate morphometric assessment of bone relationships. In cases where the panoramic radiograph reveals a possible relationship between a tooth that has undergone intervention and its contact with the adjacent maxillary sinus, evaluation by cone beam computed tomography (CBCT) can assist in dental treatment planning. This imaging modality allows for a thorough analysis of the anatomical relationship between the maxillary sinus and the roots of the upper teeth, thus overcoming the limitations of panoramic radiography, providing multiplanar views without magnification, distortion, or superimposition. 11 This technique is superior to multi-slice computed tomography due to its higher image resolution, reduced radiation exposure, and lower equipment cost. (29)

In apical periodontitis, a periodontal disease, treatment with implants and extraction of upper premolars and molars may increase the risk of pathological processes in the adjacent maxillary sinus. Of the odontogenic sinus diseases, apical periodontitis and periodontal disease account for 83% of all cases having dental origin. (30) The most frequent maxillary sinus pathologies are sinus mucosal thickening and mucous retention cysts, with a prevalence ranging from 8% to 29% and 2% to 36%, respectively. Another study has reported a prevalence rate of odontogenic maxillary sinusitis ranging from 10% to 86%.

Treatment

One of four different treatment modalities, including intra-arterial (IA)-ICT, intravenous (IV)-ICT, CCRT, and surgical resection, was selected as a primary treatment based on the TNM stage,performance status, age, and co-morbidity. ICT was administered through the IA or IV route. Superselective IA infusion of chemotherapeutic drugs was attempted via a series of processes. The contrast-enhanced tumor mass and tumor feeding vessels were confirmed via diagnostic angiographic procedures of the internal and external carotid arteries by means of transfemoral access. The internal maxillary artery was superselected with a microcatheter, and then the chemother-apeutic drug was administered via a microcatheter into the tumor-supplying artery.

The transfemoral catheter was removed on completion of the infusion. Cisplatin (100 mg/m^2) was administered via a microcatheter into the internal maxillary artery over two hours on day 1, and then 5-FU (1000 mg/m^2/day) was continuously infused from day 1 to day 5 over 120 hours through the IV route. A standard hydration and mannitol diuresis regimen were applied. The entire procedure was repeated 2–3 times every 3–4 weeks.

The IV-ICT was performed 2–3 times every four weeks as well. Cisplatin (100 mg/m^2) was administered intravenously over two hours on day 1, and 5-FU (1000 mg/m^2/day) was infused continuously from day 1 to day 5 over 120 hours through the IV route. All patients who received ICT were re-evaluated for tumor response with CT and/or MRI at least 4–6 weeks after the completion of ICT. The decision to perform surgery after ICT was based on the tumor response.

The chemotherapeutic agent used in the CCRT group was cisplatin. During radiation therapy, cisplatin (30 mg/m^2) was administered by a weekly schedule on days 1, 8, 15, 22, 29, 36, 43, and 50, or cisplatin (100 mg/m^2) was administered every 3 weeks on days 1, 22, and 43. All patients treated with CCRT were reevaluated for tumor response, and then the next treatment modality, surgical resection or salvage chemotherapy, was determined. The periodic follow-up was done at least 6–8 weeks after the completion of radiation therapy.

CCRT

CCRT is regarded as the more effective treatment because of the radiosensitizing efficacy of cisplatin compared with radiation therapy alone. Several studies have demonstrated that CCRT has a higher tumor control rate and survival rate in head and neck cancers than radiation therapy alone [9] Harrison *et al.* reported a three-year local control rate of 78% and a three-year survival rate of 42% in 12 patients with paranasal sinus carcinomas treated with cisplatin-based CCRT [10]In this study, seven patients with stage IV maxillary sinus cancer received CCRT as a primary treatment, and the objective response rate was 57%. However, the assessments of recurrence and survival rate were impossible because of small sample size and loss to follow-up.

IA Chemotherapy

The femoral artery was punctured under local anesthesia by Seldinger's method. The tip of the catheter was threaded into the external carotid artery. Fluorography was performed through amicro-catheter to determine the dominant tumor-supplying vessel with digital angiography. Cone-beam computed tomography was also used during angiography to ascertain the stained area. In cases which had multiple tumor-supplying vessels, the dose of CDDP and DOC was divided according to the stained tumor volume**.**

Conclusion

Invasive SCC can be difficult to diagnose in its early stages and might be misdiagnosed as facial pain syndromes (such as TN), which often present as a unilateral shooting pain and commonly affect branches of the trigeminal nerve. Treatment of TN is initially effective in up to 90% of patients but will dampen neural impulses,[11] disguising any alternate pathology. A careful history and extraoral and intraoral examination as well as appropriate investigations, such as a CT scan, should be undertaken before definitively diagnosing TN. If in doubt, early specialist referral to exclude an underlying malignancy is absolutely necessary.

Abstract

The pyramid-shaped maxillary sinus (or Antrum of Highmore) is the largest of the paranasal sinuses and drains into the middle meatus of the nose. The image of the body of the zygomatic bone and the temporal process of the zygomatic bone may be superimposed on the sinus on a radiograph - less with paralleling technique. Radiographically just posterior to the posterior wall of the sinus one may see a teardrop radiolucency – the pterygomaxillary fissure. In adults with a full set of teeth, the maxillary sinus floor is the strongest of the bone walls surrounding the cavity. The anatomical relation between the maxillary sinus and the teeth is a complex one, due to the variable extension of the sinus. Antral mucosa is thinner and less vascular than nasal mucosa. The blood supply to the maxillary sinus is principally derived from the posterior superior alveolar artery and infra orbital artery, both being branches of the maxillary artery. There are significantly anastomoses between these two arteries in the lateral antral wall. The greater palatine artery also supplies the inferior portion of the sinus. However, because the blood supplies to the blood supplies to the maxillary sinus are from terminal branches of peripheral vessels, significant haemorrhage during the sinus lift procedure is rare. Nerve supply to the sinus is derived from the superior alveolar branch of the maxillary division of the Trigeminal nerve. The size of the sinus will increase with age if the area is edentulous. The extent of pneumatization varies from person to person from side to side. Nonetheless, this process often leaves the bony lateral and occlusal alveolus paper thin in the posterior maxilla. The maxillary sinus bony cavity is lined with the sinus membrane, also known as the schneiderian membrane. This membrane consists of ciliates epithelium like the rest of nasal epithelium through the ostium in the middle meatus. The membrane has a thickness of approximately 0.8mm.

***Key Words**: Sinus, bony septa, pathologic conditions, sinus lift, sinus membrane*.

Introduction

The maxillary sinus is the pneumatic space that is lodged inside the body of maxilla and communicates with the environment with the environment by the way of the middle nasal meatus. It is also known as the "Antrum of Highmore" The maxillary sinus is formed by pneumatization of the maxilla and is expanded to the body of the zygoma laterally and to the palatine bone posteriorly, to a one-side volume of 15 ml, though this varies widely from individual to individual. Maxillary sinus is the first of the PNS to develop. Early diagnosis is essential in order to avoid high morbidity and mortality associated with the destructive disease and to instigate treatment before irreversible condition arise. The inflammatory lesions that affect the paranasal sinuses receive the generic denomination sinusitis; maxillary sinus is the most commonly affected. This inflammation can have various origins, including the tooth. The maxillary sinus belonging to the nasal and oral cavity is the most susceptible of the all sinus to the invasion by pathogenic bacteria, either through their communication with the nasal cavity, or the product of odontogenic infection.

Anatomy of Maxillary Sinus

The maxillary sinus begins to develop between second and third month of pregnancy, with an evagination of nasal passage lateral wall mucosa. The maxillary sinus is a pyramid shaped cavity with its base adjacent to the nasal wall and apex pointing to the zygoma. The size of the sinus is insignificant until the eruption of permanent dentition. The average dimensions of the adult sinus are 2.5 to 3.5 cm wide, 3.6 to 4.5 cm tall, and 3.8 to 4.5 cm deep. It hasan estimated volume of approximately 12 to 15cm. Anteriorly, it extends to the canine and premolar area. The sinus floor usually has its most inferior point near the first molar region. The size of the sinus will increase with age if the area is edentulous. The extent of pneumatisation varies from person to person and from side to side(1). The close anatomical relationship of the maxillary sinus with the roots of maxillary molars and premolars renders this anatomical region susceptible to morbid situations resulting from damage to, and therapeutic intervention in the dentoalveolar environment.The loss of the teeth interrupts the cybernetic connections of the stomatognatic system, determining maxillary and mandibular structural changes that represent signs of inactivity atrophy due to functional unload. Modifications in the lateral area of the edentulous maxilla may affect

more than 70% of its height and width(2). The sinus may 'invade' the alveolar bone surrounding the roots of the posterior maxillary teeth, where it may pose a surgical hazard when extracting teeth in this area. The formation of septa (ie,Underwood's septa), both complete and incomplete, within the sinus is often noted(3).

Bony Septa

Maxillary sinus septa were first described by Underwood in 1910. They are walls of cortical bone within the maxillary sinus, their shape has been described as an inverted gothic arch arising from the inferior or lateral walls of the sinus, and may even divide the sinus into two or more cavities. Radiographic identification of these structures is important, since the design of the lateral window during sinus lift procedures is based on the presence and size of maxillary sinus septa(4). Inside the maxillary sinus, bony septa originating in the sinus floor are often found. They are called Underwood septa, they may divide the back part of the sinus into multiple compartments known as posterior recesses. They may even occasionally reach from the base to the upper sinus wall, creating two sinuses. Estimates of the prevalence of such septa have ranged from 16 to 58%.The formation of Underwood septa may be linked to the fact that teeth are lost at different times. The edentulous areas may resorb in a manner that results in a difference in level between the two adjacent portions of the sinus floor(5). Between 13 and 35.3% of maxillary sinuses have septa; to avoid complications during sinus lifting a meticulous study of the sinus is necessary, preferably by computed tomography, as panoramic radiography has been to shown to have a low sensibility and specificity in the identification of these structures.

According to Underwood(6), the maxillary sinus floor is frequently divided into three basins: a small anterior one over the premolar region; a large median one descending between the roots of the first and second molars, and a small posterior one corresponding to the third molar region. These three sections of the floor of the sinus, which are often marked off by ridges, rising sometimes to distinct septa, correspond to three de ned periods of tooth activity, separated by intervals of time: the anterior portion corresponds to the position of the eruption of the milk molars (between 8 months and 2 years); the middle portion corresponds to the eruption of the first and second permanent molars (from 5 to 12 years); and the posterior, corresponds to the eruption of the third molars (16 to 30 years). The origin of the septa is wholly dental, and is due to the persistence of the intervening partitions when the rest of the

bony floor sinks down between the dental roots during tooth eruption, leading to the location of septa between the roots of two adjacent teeth. Underwood observed the existence of another type of septa, indicating that it must have a different origin as it seemed to be unrelated with teeth.

Krennmair et al. (7) classified septa into primary and secondary: primary septa corresponding to those first described by Underwood, arising from the development of the maxilla; and secondary septa arising from irregular pneumatization of the sinus floor following tooth loss. Other authors (8,9,10) when observing maxillary sinus septa, classified them as primary septa if they were located superior to a maxillary tooth; and other septa, for septa located superior to an edentulous ridge, as they could be either primary or secondary septa, or a combination of both types.

Maxillary Sinus Membrane

The maxillary sinus is lined with a respiratory mucosa similar to that of the nose and other paranasal sinuses. It consists of a mucoperiosteum with 3layers: an epithelial covering, a lamina propria, and periosteum.The maxillary sinus membrane varies in thickness, but is generally 0.3 to 0.8 mm. The epithelial lining is a single layer of pseudo stratified columnar ciliated epithelium with few blood vessels and is thicker than that of the other paranasal sinuses. Numerous goblet cells are present within the mucosa and are the major source of mucous secretion. The highest density of these cells is located near the sinus ostium. The density of ciliated cells is high, ranging from 91.3% to 97.7%, except near the ostium, where the density is decreased by half(11). The lamina propria consists of a thin layer of connective tissue with few elastic fibres. It is thickest at the medial wall and contains more seromucous glands than the lateral wall. The periosteum is tightly bound to the overlying lamina propria, but is easily detachable from the underlying bone, making membrane separation during the sinus lift procedure relatively easy.Any factors that compromise mucous production, ciliary function, or patency of the ostium can increase the risk of sinusitis. As a result, with sinus elevation augmentation surgery, it is important to maintain membrane integrity to allow for confinement of the particulate graft and to decrease the risk of infection(12). The maxillary sinus bony cavity is lined with the sinus membrane, also known as theSchneiderian membrane. This membrane consists of ciliated epithelium like the rest of the respiratory tract. It is continuous with, and connects to, the nasal epithelium through the ostium in the middle meatus. The sinus floor tends to lower craniocaudally as the alveolar ridge is resorbed in the opposed direction. It is the

lack of vertical posterior maxillary bone that often necessitates the use of bone grafts or sinus-lifting procedures prior to implant rehabilitation. Progressive resorption of the posterior maxillary edentulous ridge follows a well-defined path that differs from that of the anterior regions and includes repeatable, predictable morphologic changes. Cawood and Howell's system for classifying the degrees of atrophy based on the morphologic differences in the residual ridge is extremely useful for presurgical diagnostic assessment, as the ridge appearance is connected to the horizontal and vertical size of bone available for implants.

Fungal Infections

A variety of different causative organisms are responsible for paranasal mycoses, Aspergillus and Mucor being the commonest. Paranasal mycoses manifests as two distinct entities, a benign or non invasive infection and the more serious invasive infection, which occurs in immunocompromised individuals(13). Early diagnosis is vital in these infections as delay in initiation of treatment can be life threatening due to propensity of the fungi to invade adjacent blood vessels and connective tissues produces thrombosis and ultimately necrosis of the hard and soft tissues. Although the fungi and spores of mucorales shows minimal intrinsic pathogenicity towards normal persons, they can initiate aggressive and fulminating infection in the patients whose resistance is lowered by immunocompression, diabetes, malignant disease, burns, trauma, and rarely steroids(14). The effective management of paranasal sinus fungal infection requires early diagnosis, histological classification and surgery and when appropriate chemotherapy.Treatment in invasive fungal sinusitis involves radical surgery in addition to intravenous amphotericin B/lipid complex of liposomal amphotericin B with or without flucytosine. The optimum dose and duration of treatment is still unclear. Endoscopic surgery has been found to be feasible and efficient, enabling excellent local control and less morbidity than traditional approaches. Sinus surgery must be performed as soon as feasible(15).

Pathologic Conditions of Maxillary Sinus

Diseases of the maxillary sinus are comparatively frequent, even in apparently young individuals with rates in excess of one in five individuals examined using the Waters projection (mucosal thickening 12.3%; cysts or polyps 7.2%; opacified sinus 3.3%)(16). For this reason, it is incumbent upon the dental practitioner to understand the panoramic

radiological features of disease and normal variations within the paranasal sinuses. Certainly the patient should not be referred to an ear, nose and throat specialist for every instance of antral mucosal thickening or mucous retention cyst, nor should the dentist ignore features that possibly reflect an early malignancy. The reputation of a practitioner is greatly enhanced given appropriate referrals that can make the difference between life and death. Failure to diagnose, on the other hand, can result in notoriety. Nortje et al (17) were among the first to comprehensively study the appearance on panoramic dental radiographs of pathological conditions affecting the maxillary sinuses, comparing inflammatory conditions of dental origin, iatrogenic disease/foreign bodies, non-odontogenic inflammatory conditions, cysts, benign neoplasms, malignant neoplasms and dysplasia affecting the maxilla. Primary malignancies affecting the maxillary sinus include squamous-cell carcinoma, adenoid cysticcarcinoma and adenocarcinoma(18). The maxillary sinus may also be affected secondarily by extension malignancies of the oral soft tissues or jaw, and also, although rare, is the site ofmetastases from distant sites(19). Owing to the radio-opacity, roots or whole teeth displaced into the sinus are readily apparent even when not centred within the image layer. These need to be differentiated from sinus bone nodules and antroliths (calcified stones arising in the antral lining) both of which entities could be mistaken for teeth or displaced roots(20). Foreign bodies, such as bullets, are clearly demonstrated; however care needs to be made to differentiate between clearly demarcated real images, and blurred magnified ghost images of foreign bodies or jewellery more distally and lower placed in or on the contralateral side of the face. Oroantral fistulas following dental extraction are only noticeable on panoramic radiography when large and within the panoramic image layer.

The growth of tumours within the maxilla is not concentric; hence, the site of origin is not necessarily the epicentre of the lesion. The maxillary sinus, constituted the path of least resistance for the growth of such maxillary lesions as cysts and benign neoplasms. Even very large benign tumours and cysts might be present without resulting in clinically noticeable jaw expansion. Hence, the panoramic radiograph is of value in detection of unsuspected disease.

Antral malignancies are usually insidious and produce clinical signs and symptoms relatively late, whentheprognosisisoftenquite poor. Panoramic radiographs have been found of utility in detection of antral carcinoma, particularly that affecting the posterior wall of the sinus(21). Caution should be used in that the panoramic radiograph is not the technique of choice for viewing the maxillary sinuses, however, it is incumbent on the dentist to evaluate the portion of the maxillary sinus shown in the panoramic radiograph made for other purposes. This might well be the first sign of disease and the only reason for pursuing further diagnostic

tests. Early detection of such sinister occurrences improves the prognosis for the unfortunate patient.

Maxillary Sinusitis

Sinusitis is a swelling of the inner lining of the sinuses The sinuses are the spaces between the bones in the face where air passes and where a fluid called mucus drains into the nose In sinusitis, the swelling blocks the openings in the sinuses through which mucus drains into the nose When mucus cannot drain properly, the pressure of the blocked fluid inside the sinuses can be painful.

Sinusitis can be acute (going on less than four weeks), sub acute (4–8 weeks) or chronic (going on for 8 weeks or more All three types of sinusitis have similar symptoms, and are thus often difficult to distinguish. Birt stated that otolaryngologists see scores of patients with vague discomfort in the forehead, between the eyes, and across the nose and cheeks.Patients invariably ascribe their symptoms to sinus disease, and are later surprised to discover that they are not infected. In fact, chronic sinusitis is not particularly common, and many headache patientswithautonomicfeatureswill probably have muscle tension headaches or migraines(22). Sinus headache is commonly diagnosed, and patients with headache often cite sinus pain and pressure as a cause of their headaches. A high frequency of diagnosis of sinus headache, which specialists consider to be relatively rare, among patients meeting International Headache Society (IHS) diagnostic criteria for migraine raises the possibility that migraine and perhaps other headache types are sometimes mistaken for sinus headache.

In some instances, chronic maxillary atelectasis can present with enophthalmos secondary to collapse of the maxillary sinus. For reasons that are unclear, the sinus component of the disease remains asymptomatic and is discovered only after thorough evaluation of the enophthalmos. Isolated sphenoid sinusitis is often misdiagnosed because of its rarity and varied clinical presentation. Presentation is often both subtle and suggestive of other intracranial etiologic sites, as determined by the anatomic relationships of the sphenoid sinus(23).

Sinusitis is among the most commonly encountered diseases of childhood and has been the major area of interest for many otolaryngologists, allergists, and paediatricians. Allergies and viral upper respiratory infections are among the most common predisposing factors of sinus disease. Every child with sinusitis is a candidate for an allergy evaluation.

Sinus Lift

The lack of bone volume can be treated with various bone grafting techniques before the implant placement. Boyne & James (1980) was the first to introduce maxillary sinus floor augmentation with autologous bone graft. This technique has been modified and improved by Tatum (1986) who introduced the lateral approach by fenestrating the buccal wall of maxillary sinus and lifting the Schneiderian membrane. This technique was modified by Wood and More in 1988.

The sinus floor augmentation procedure can be divided into two different techniques. The first of the two techniques is called the osteotomy technique and it is performed by the use of osteotomes to create a controlled fracture of the floor of the maxillary sinus. This method creates space by elevating the sinus membrane and provides room for the dental implant and bone grafting material. The advantage of this technique is that it is less invasive and thereby reduced surgical time and lower morbidity compared to other sinus lift techniques. This technique is suggested to be used when the vertical bone height is more than 4-6mm. The second technique is the lateral window technique and is performed by surgical preparing of the bone, lateral to the maxillary sinus, and thereby exposing the Schneiderian membrane which will be elevated. The bone graft material is carefully packed and placed on the sinus floor. [24] This technique is more invasive than the osteotome technique due to the fenestration of the lateral sinus wall. The lateral window technique is preferred when there is less than 6 mm residual bone height.

Direct Sinus Augmentation Technique (DSAT)

Those cases that has residual alveolar bone (RAB) height 5 mm or below was considered for the direct technique. Autogenous bone grafts was harvested by shaving the mandibular bone from external oblique ridge area or chin area. A bone mill was used to grind the bone shaving intofine particles. After adequate local anesthesia and preparation, a surgical incision was placed on the crest of the RAB at most appropriate area, with vertical releasing curvilinear incisions flaring into the vestibule. Full- thickness, subperiosteal labial, and palatal flaps were raised, reflected. Care was taken to keep the base of flap broad as well as adequate buccal and palatal tissue for closure. After elevation, the anterolateral wall of maxillary sinus was visualized. Care was taken to identify and protect infraorbital nerve, if encountered. The dimension of osteotomy was determined based on clinical and radiographic examinations as well as the extent of edentulous span. A buccal bone window was made on exposed wall of maxillary sinus using a postage stamp method. The bony wall was gently manipulated with

sinus membrane elevators without damaging Schneiderian membrane. The previously obtained graft material was then placed and packed. The implant was placed on same sitting with help of a stent which was positioned, then removed, and the site was checked for appropriate faciolingual and mesiodistal positioning. Any obvious abnormal crestal defects required slight modification of the position(25).

Indirect Sinus Augmentation Technique (ISAT)

Indirect sinus augmentation is done for cases with RAB height of 6-8 mm. The RAB to receive the implant was given local anesthesia and perforated using a small rounded drill. A pilot drill was placed in marked implant site to establish the axis of implant recipient site. Following the pilot drill, subsequently increasing diameter of drills were used to enlarge implant recipient site till the desired diameter corresponding to implant diameter was reached. The height of drill was maintained 2 mm short of sinus floor. The indirect sinus lift was done by insertion of correct caliber osteotome and working up through successively greater instrument diameters, until the sinus floor was fractured and elevated up. The sinus floor was carefully fractured, separated from the Schneiderian membrane avoiding damage to membrane using a surgical mallet with controlled force. If required, autogenous graft material was inserted within the socket. The material was displaced apically with help of larger-diameter instruments, thereby lifting the membrane and condensing graft material between the latter and sinus floor. The implant was then placed immediately in the prepared site. 3-0 Vicryl sutures were used to close the surgical wound. Antibiotic coverage, pain killers, and nasal decongestants were prescribed for 5 days. The patients were monitored on a periodic basis both clinically and radiologically(26).

Bone Healing

Bone healing after graft placement takes place in two phases: Repair with an inflammatory response and bone remodelling. In the first phase a blood clot is formed in the injured area where the outer area of the local bone becomes necrotic and the capillaries start to develop and further on migration of inflammatory cells e.g. lymphocytes, granulocytes and monocytes occur. This action restores blood flow and after 1-3 days an inflammatory response is active and granulation tissue is starting to form. The granulation tissue will mature to a collagen matrix and mesenchymal stem cells begin to differentiate into osteoblasts cells forming new bone. During the second phase, the bone remodel, and is replaced by a more mature lamellar

bone and a complete regeneration of a defect occurs when all bone is replaced with lamellar bone.

Conclusion

The maxillary sinus is one of the four paranasal sinuses. The maxillary sinus is the largest of the paranasal sinuses. The two maxillary sinuses are located below the cheeks, above the teeth and on the sides of the nose. The maxillary sinuses are shaped like a pyramid and each contain three cavities which point sideways, inwards, and downwards. Most of the maxillary sinuses have septa; to avoid complications during sinus lifting a meticulous study of the sinus is necessary, preferably by computed tomography, as panoramic radiography has been to shown to have a low sensibility in the identification of these structures.The sinuses are tiny air-filled holes found in the bones of the face which reduce skull weight, produce mucus, and affect the tone quality of a person's voice. The maxillary sinus drains into the nose through a hole called the ostia. When the ostia becomes clogged sinusitis can occur. The ostia of the maxillary sinus often clog because the ostia are located near the top of the maxillary sinus causing drainage to be difficult. Maxillary sinusitis or an infection of the maxillary sinus can have the following symptoms: Fever Pain or pressure in face near the cheek bones ,Toothache, Runny nose ,Sinusitis are the most common of maxillary sinus illnesses and is usually treated with prescription antibiotics.

Abstract

Programmed cell death plays critical roles in a wide variety of physiological processes during fetal development and in adult tissues. In most cases, physiological cell death occurs by apoptosis as opposed to necrosis. Defects in apoptotic cell death regulation contribute to many diseases, including disorders where cell accumulation occurs (cancer, restenosis) or where cell loss ensues (stroke, heart failure, neurodegeneration, AIDS). In recent years, the molecular machinery responsible for apoptosis has been elucidated, revealing a family of intracellular proteases, the caspases, which are responsible directly or indirectly for the morphological and biochemical changes that characterize the phenomenon of apoptosis. Diverse regulators of the caspases have also been discovered, including activators and inhibitors of these cell death proteases. Inputs from signal transduction pathways into the core of the cell death machinery have also been identified, demonstrating ways of linking environmental stimuli to cell death responses or cell survival maintenance. Knowledge of the molecular mechanisms of apoptosis is providing insights into the causes of multiple pathologies where aberrant cell death regulation occurs and is beginning to provide new approaches to the treatment of human diseases.

Key Words*: apoptosis, caspases, death domain, death effector, card protein*

Introduction

Apoptosis is a morphological phenomenon. As viewed with the assistance of the light (or, preferably, the electron) microscope, the characteristics of the apoptotic cell include chromatin condensation and nuclear fragmentation (pyknosis), plasma membrane blebbing, and cell shrinkage. Eventually, the cells breaks into small membrane-surrounded fragments (apoptotic bodies), which are cleared by phagocytosis without inciting an inflammatory response. The release of apoptotic bodies is what inspired the term “apoptosis” from the Greek, meaning “to fall away from” and conjuring notions of the falling of leaves in the autumn from deciduous trees.[1]

Apoptosis is caused by Caspases

Activation of a family of intracellular cysteine proteases which cleave their substrates at aspartic acid residues, known as caspases for *C*ysteine *Asp*artyl-specific Prote*ases*. These proteases are present as inactive zymogens in essentially all animal cells, but can be triggered to assume active states, generally involving their proteolytic processing at conserved aspartic acid (Asp) residues. During activation, the zymogen pro-proteins are cleaved to generate the large (~20 kd) and small (~10 kd) subunits of the active enzymes, typically liberating an N-terminal prodomain from the processed polypeptide chain. The active enzymes consist of heterotetramers composed of two large and two small subunits, with two active sites per molecule.[2] Analysis of the structures of the active sites of these enzymes, experiments with combinatorial peptide libraries, and other data suggest that caspases recognize the Asp residues they cleave within the context of tetrapeptide motifs, where the most proximal (N-terminal) residue recognized is designated P4 (position #4) and target Asp is P1 (position #1), and where cleavage occurs at the peptidyl bond distal (C-terminal) to the targeted Asp. This information about the structures and mechanisms of caspases has been exploited for developing small-molecule inhibitors, which are finding their way into clinical trials for stroke, liver failure, inflammatory diseases, and a wide variety of other ailments.[3]

The observation that caspases cleave their substrates at Asp residues and are also activated by proteolytic processing at Asp residues makes evident that these proteases collaborate in proteolytic cascades, whereby caspases activate themselves and each other. In humans and mice, approximately 14 caspases have been identified. They can be subgrouped according to either their amino acid sequence similarities or their protease specificities. From a functional perceptive, it is useful to view the caspases as either upstream (initiator) caspases or

downstream (effector) caspases.[4] The proforms of upstream initiator caspases possess large N-terminal pro-domains, which function as protein interaction modules, allowing them to interact with various proteins that trigger caspase activation. In contrast, the proforms of downstream effector caspases contain only short N-terminal prodomains, serving no apparent function. Downstream caspases are largely dependent on upstream caspases for their proteolytic processing and activation. Accordingly, the sequence of the cleavage sites separating the large and small subunits of the zymogen forms of the effector caspases generally match the preferred tetrapeptide specificities of the upstream initiator caspases. Similarly, examination of the cleavage sites of multiple cellular proteins, which have been identified as caspase substrates and which are known to undergo processing during apoptosis, reveals (in most instances) coincidence with the preferred tetrapeptide sequences cleaved by the effector caspases.[5] These substrates of effector caspases include protein kinases (often separating the autorepressing regulatory domains from catalytic domains) and other signal transduction proteins, cytoskeletal and nuclear matrix proteins, chromatin-modifying (eg, polyADPribosyl polymerase) and DNA repair proteins, and inhibitory subunits of endonucleases (CIDE family proteins).

Caspase Activation Mechanisms

A diversity of mechanisms exists for activating initiator caspases, thus setting the wheels of the apoptotic machinery in motion. However, fundamentally, the biochemical mechanisms appear to be remarkably similar and can be explained by a single model, known as the induced proximity model.[6] The induced proximity model is predicated on the empirical observation that the zymogen forms of unprocessed caspases are not entirely inactive but rather possess weak protease activity (measured in some cases at ~1% of the fully active enzymes). When brought into close apposition through protein interactions, the zymogens can *trans*-process each other, producing the fully active proteases.

Though many pathways for activating caspases may exist, only two have been elucidated in detail. One of these centers on tumor necrosis factor (TNF) family receptors, which use caspase activation as a signaling mechanism, thus connecting ligand binding at the cell surface to apoptosis induction.[7] The other involves the participation of mitochondria, which release caspase-activating proteins into the cytosol, thereby triggering apoptosis. The death receptor and mitochondrial pathways for caspase activation are sometimes referred to as the extrinsic and intrinsic apoptosis pathways, respectively, though this is an oversimplification.

Also, though commonly viewed as separate pathways and capable of functioning independently, cross-talk can occur between these pathways at multiple levels, depending on the repertoire of apoptosis-modulating proteins expressed.[8]

Protein Domains Associated with Apoptosis Regulation

The proteins that directly control the intrinsic, extrinsic, and other less understood caspase activation pathways often exist as families that can be recognized based on their amino acid sequence and/or structural similarity.[9] Moreover, interactions among these proteins are commonly mediated by domains that are intimately associated with apoptosis regulation, including caspase-associated recruitment domains (CARDs), death domains (DDs), death effector domains (DEDs), Bcl-2 homology (BH) domains of Bcl-2 family proteins, baculovirus inhibitor of apoptosis proteins (IAP) repeat (BIR) domains of IAP family proteins, and NB-ARC domains representing the nucleotide-binding oligomerization domains of CED-4/Apaf-1 family proteins. A summary of the proteins that constitute the known members of these families of apoptosis regulators follows, along with information about their mechanisms and some examples of their relevance to diseases.

Death Domain Proteins

The DD is a protein interaction module consisting of a compact bundle of six α-helices. DDs bind each other, probably forming oligomers of unknown stoichiometry. Specificity for partner selection among DDs is dictated by differences in surface residues. Several of the members of the TNF family of cytokine receptors contain DDs in their cytosolic regions, including TNFR1, Fas (Apo1), DR3 (Apo2), DR4 (TrailR1), DR5 (TrailR2), DR6 in humans, mice, and probably other mammals. The p75 nerve growth factor receptor (p75-NGFR) also contains a modified (type II) DD and has been reported to induce apoptosis under some circumstances.[10] The TNF family receptors, TNFR1, DR3, and DR6, are known to bind an adapter protein, Tradd, via its homologous DD. The DD of Tradd is capable of binding certain other DD-containing proteins, including the adapter protein Fadd. The Fadd (Mort1) protein contains two protein interaction modules, a DD and a DED. Fadd links TNF family death receptors to caspases, using its DD to bind Tradd or to interact directly with the cytosolic DD of the TNFR family member Fas, and employing its DED to bind DED-containing caspases (see below). Experimental evidence has demonstrated the presence of Fadd within the receptor complexes of all known DD-containing members of the TNF family except p75-NGFR. Thus, this protein plays a central role in linking caspases to TNF family

death receptors, a notion borne out by gene ablation studies in mice, which have demonstrated an inability of TNFR1, Fas, and other death receptors tested thus far to induce apoptosis in the absence of Fadd.[11]

An analogous mechanism for recruiting pro-caspases to death receptor complexes has been revealed in the case of Raidd (Cradd). This adapter protein contains a DD in combination with a CARD, allowing it to bind the corresponding CARD found within the prodomain of pro-caspase-2.[12] Based on the aforementioned Fadd knockout studies, however, it remains questionable how important this alternative pathway for caspase activation is.

Additional DD-containing proteins have been implicated in apoptosis, such as the DAP kinase, which modulates apoptosis induction by TNF family death receptors through mechanisms that are not understood.[13] This kinase has been implicated in suppression of metastasis. Several cytoskeleton-associated ankryin family proteins contain DDs, but their relevance to apoptosis remains uncertain. Given evidence, however, that caspase-8 activation is triggered by suspension of adherent epithelial cells, an event that disturbs the cytoskeleton, it is intriguing to speculate a possible role in the phenomenon of anoikis (ie, apoptosis induced by depriving cells of integrin-mediated attachments to extracellular matrix).[14] Avoidance of anoikis represents an important aspect of tumor invasion, metastasis, and angiogenesis. It is also fundamental to correct positioning of cells during development, possibly accounting for the embryonic lethality of Fadd and caspase-8 gene ablation in mice.

DDs, however, are not always involved in caspase activation or apoptosis induction. In fact, DDs have been found in proteins involved in two other receptor signaling systems, namely Toll family receptors and UNC family receptors. Nevertheless, some of the signal transduction pathways in which non-caspase-activating DD proteins are involved at least indirectly regulate apoptosis through effects on NF-κB, suppressing rather than inducing apoptosis. For example, the RIP protein binds Tradd and activates kinases that induce degradation of IkB, thus releasing NF-κB so that it can translocate to the nucleus and fulfill its function as a transcription factor.[15] Among NF-κB-inducible genes are several that block apoptosis, including anti-apoptotic Bcl-2 family members Bfl-1 (A1) and Bcl-X, and IAP family member cIAP2 and possibly cIAP1 and XIAP. The dual function of Tradd, as a partner for both caspase-activator Fadd and NF-κB activator RIP, causes many of the TNF family receptors to nullify their own apoptosis-inducing activity. Thus, TNFR1, DR3, and DR6 are uncertain apoptosis inducers unless NF-κB induction is inhibited.[16] In contrast,

Fas and the Trail receptors DR4 and DR5 only rarely activate NF-κB, probably because these receptor complexes contain Fadd but not Tradd. In fact, it is because Trail receptors (DR4 and DR5) do not induce NF-κB-mediated pro-inflammatory responses *in vivo* that the Trail ligand is under consideration for clinical use in the treatment of cancer, whereas NF-κB-inducing TNF-α proved to be unacceptable.[17]

Multiple mechanisms for modulating signaling by TNF family death receptors probably exist. One that acts directly on DDs involves the silencer of death domains protein (SODD), also know as BAG4.[18] SODD contains a C-terminal BAG domain that allows it to bind Hsc70/Hsp70 family molecular chaperones. An N-terminal domain in SODD mediates its interactions with the DDs of TNFR1 and DR3. Overexpression of SODD prevents TNFR1 and DR3 from spontaneously aggregating and signaling in the absence of ligand. Though unproven, it has been suggested that recruitment of Hsp70/Hsc70 to these death receptors induces conformational changes in the DD that prevent self-oligomerization until the receptors are appropriately triggered by cognate ligands.[19]

Another resistance mechanism has been attributed to FAP, a protein tyrosine phosphatase that uses PDZ domains to interact with the C-termini of Fas and p75-NGFR, suppressing apoptosis signaling by these receptors through uncertain mechanisms.[20] Overexpression of FAP-1 in tumors has been associated with resistance to Fas-induced apoptosis.

Death Effector Domain (DED) Proteins

The structure of the DED is similar to the DD, comprised of 6 α-helices. DEDs are found in the initiator caspases, caspase-8 and -10 in humans (a caspase-10 orthologue has yet to be identified in mice). The prodomain regions of pro-caspase-8 and -10 contain two tandem DEDs, which are responsible their interactions with the DED of Fadd, and thus mediate their recruitment to death receptor complexes. Multiple DED-containing modulators of apoptosis have been identified. Flash, for example, is a large protein containing two DED-like domains which reportedly enhances caspase-8 activation by Fas. DEDD (DEFT) is another DED-containing protein which reportedly enhances Fas-induced apoptosis. DEDD contains an N-terminal DED and a C-terminal histone-like domain.[21] DEDD is present in the cytosol, but during Fas-induced apoptosis it translocates to nuclei in a caspase-dependent manner,

localizing to nucleoli and possibly shutting off ribosomal RNA gene transcription. DEDD associates with Fadd, and to some extent pro-caspase-8, via DED-mediated interactions.[22]

In contrast to Flash and DEDD (DEFT), which enhance Fas-induced apoptosis, the DED-containing protein Flip (also known as Flame, CASH, Clarp, MRIT, Casper, I-Flice, Usurpin) is capable of suppressing caspase-8 activation by Fas and other death receptors. Flip shares extensive amino acid sequence similarity with pro-caspase-8 and -10, containing two N-terminal DEDs followed by a pseudo-caspase domain that lacks critical residues required for protease activity, including the catalytic cysteine.[23] Flip associates with pro-caspase-8 and also competes with pro-caspases-8 and -10 for binding to Fadd, thus squelching death receptor signaling. Interestingly, some tumors have been reported to contain inappropriately elevated levels of Flip, rendering them resistant to apoptosis induction by Fas-expressing CTLs.[24] Though controversial, Flip-mediated resistance to Fas may even permit tumor cells to tolerate expressing FasL, using this death ligand as a weapon against neighboring normal cells and triggering apoptosis of immune cells. Interestingly, some viruses also encode DED-containing proteins analogous to Flip that similarly suppress apoptosis induced by Fas. By thwarting Fas-induced apoptosis, viruses presumably can avoid CTL-mediated eradication of the host cells they infect, allowing more time for viral replication.

Decreased expression of the DED-containing apoptosis suppressor, Flip (Usurpin), occurs in myocardial tissue damaged by ischemia-reperfusion injury, suggesting increased sensitivity to apoptosis induction via the death receptor pathway.[25]

CARD Family Proteins

Several pro-caspases contain N-terminal CARDs in their prodomains, including caspases 1, 2, 4, 5, and 9 in humans and caspases 1, 2, 9, 11, and 12 in mice. (To date, orthologues of human caspases 4 and 5 have not been observed in mice and conversely orthologues of murine caspases 11 and 12 have not been found in humans.) Roles for CARD-carryingcaspases in diseases have been revealed through gene ablation studies in mice. For example, caspase-1 knockout mice exhibit marked resistance to endotoxin-induced sepsis.[26] Caspase-1, as well as caspase-2 and caspase-11, knockout mice also suffer less tissue loss in stroke models. Inhibition of caspase-1 also slows progression in a mouse model of Huntington’s disease. In addition, cells from caspase-12 knockout mice are resistant to apoptosis induced by amyloid β-peptide, a finding of potential relevance to Alzheimer’s disease. In this regard, caspase-12 appears to be associated with the endoplasmic reticulum

(ER) and becomes specifically activated by ER stress, thus linking ER damage to a caspase activation pathway independently of the mitochondrial (cytochrome c) and death receptor (TNF family) pathways.[27]

The overall structure of the CARD is similar to DDs and DEDs, comprised of 6 α-helices.Homotypic interactions among CARD-carrying proteins play important roles in caspase activation throughout animal evolution. One of the paradigms used for caspase activation is embodied in CED-4/Apaf-1 family proteins. These proteins contain a CARD domain in combination with a nucleotide-binding oligomerization domain, known as a NB-ARC (NACHT) domain for *N*ucleotide-*B*inding domain homologous to *A*paf-1, *C*ED-4 and plant *R* gene products. The N-terminal CARDs of Apaf-1 in humans and CED-4 in the nematode *Caenorhabditiselegans* mediate interactions with the CARDs of specific initiator caspases, pro-caspase-9 and pro-CED-3, respectively.[28] Oligomerized Apaf-1 and CED-4 activate caspases by the induced proximity method.

With the CED-4 protein of *C. elegans*, binding and activation of the caspase pro-CED-3 is spontaneous. In contrast, the human and *Drosophila* Apaf-1 proteins contain an additional regulatory domain, comprised of several WD repeat domains, which renders them dependent on cytochrome c.[29] Though less is known about the fly protein, biochemical analysis of human Apaf-1 using *in vitro* reconstituted systems with purified components indicates that cytochrome c, in combination with dATP, induces oligomerization of Apaf-1 molecules, followed by binding to and activation of pro-caspase-9. Several mechanisms for suppressing caspase activation by Apaf-1 have been identified, including expression of a shorter noncatalytic isoform of pro-caspase-9 that competes with full-length caspase-9 for binding Apaf-1, phosphorylation of human caspase-9 by the kinase Akt, overexpression of heat shock proteins, and alkaline pH.[30]

IAP Family Proteins

The IAPs represent a family of evolutionarily conserved apoptosis suppressors. IAPs are found in the genomes of mammals, insects, and certain animal viruses. All members of this family, by definition, contain at least one copy of a so-called BIR (baculovirusiap repeat) domain, a zinc-binding fold important for their anti-apoptotic activity. In addition to 1 to 3 copies of a BIR domain, many IAP family proteins also contain other domains, including RING zinc-fingers, CARDs, Ubiquitin-conjugating enzyme (E2s) domains, or putative nucleotide-binding domains. Interestingly, the RINGs of IAPs have recently been implicated

in interactions with the cellular components of the ubiquitination machinery, thus controlling turnover of these proteins and possibly other proteins with which they associate. Also, the BIR-containing protein, Apollon (Bruce) contains a domain with ubiquitin-conjugating enzyme (E2) activity, further suggesting links of BIR family proteins to the cellular ubiquitination machinery.[31] Though the overall relevance to apoptosis of this protein remains uncertain, antisense-mediated down-regulation of Apollon reportedly can sensitize tumor cell lines to apoptosis induced by anti-cancer drugs. In this regard, it bears noting that the mere presence of a BIR domain does not necessarily indicate anti-apoptotic activity. For example, BIR-containing proteins, which regulate mitosis and meiosis but have no apparent effect on cell death regulation, have been studied in yeast and *C. elegans*.[32]

Though IAP family proteins may possess other functions, several of them have been shown to bind and potently inhibit activated caspases. Among the caspases inhibited by human IAP family members XIAP, cIAP1, and cIAP2 are the effector caspases-3 and -7, as well as the initiator caspase-9. Suppression of the effector caspases maps to the N-terminal half of the protein in the region encompassing the first two BIR domains, BIR1 and BIR2, whereas the third BIR domain is required for suppression of caspase-9. Importantly, IAPs are selective caspase inhibitors and lack activity against many members of the caspase family of cell death proteases. This stands in marked contrast to the baculovirus p35 protein, an apoptosis suppressor that displays broad activity against caspases but for which no cellular homologue has been identified.[33]

Human IAPs can arrest apoptosis induced via either the intrinsic (mitochondrial) or extrinsic (death receptor) pathways, probably because they target effector caspases common to both pathways. In contrast, insect IAPs may inhibit primarily initiator caspases within the mitochondria-dependent pathway, possibly reflecting the later evolution of the death receptor (TNF family) pathway.[34]

Bcl-2 Family Proteins

The mitochondria-dependent pathway for apoptosis is governed by Bcl-2 family proteins. Bcl-2 family proteins are conserved throughout metazoan evolution, with homologues found in mammalian, avian, fish, and amphibian species, as well as in invertebrates such as *C. elegans*, *Drosophila*, and marine sponges. Several types of animal viruses also harbor Bcl-2 family genes within their genomes. Both pro- and anti-apoptotic Bcl-2 family proteins exist, and many of these proteins physically bind each other, forming a complex network of homo-

and heterodimers.[35] The relative ratios of anti- and pro-apoptotic Bcl-2 family proteins dictate the ultimate sensitivity or resistance of cells to various apoptotic stimuli, including growth factor/neurotrophin deprivation, hypoxia, radiation, anti-cancer drugs, oxidants, and Ca^{2+} overload. Not surprisingly, then, alterations in the amounts of these proteins have been associated with a variety of pathological conditions, characterized by either too much (cell loss) or too little (cell accumulation) cell death. These diseases include cancer, autoimmune disorders such as lupus (where a failure to eradicate autoreactive lymphocytes occurs), immunodeficiency associated with HIV infection, and ischemia-reperfusion injury during stroke and myocardial infarction, among others.

Based on their predicted (or experimentally determined) three-dimensional structures, Bcl-2 family proteins can be broadly divided into two groups. One subset of these proteins is probably similar in structure to the pore-forming domains of bacterial toxins, such as the colicins and diphtheria toxin. These α-helical pore/channel-like proteins include both pro-apoptotic proteins (Bcl-2, Bcl-X_L, Mcl-1, Bfl-1, Bcl-W, and possibly Boo), as well as pro-apoptotic proteins (Bax, Bak, Bok, and Bid). Most of these protein in this subcategory can be recognized by conserved stretches of amino acid sequence homology, including the presence of Bcl-2 homology (BH) domains BH1, BH2, BH3, and sometimes BH4. However, this is not uniformly the case, as the Bid protein contains only a BH3 domain but has been determined to share the same overall protein fold with Bcl-X_L.[39] Where tested, these proteins, including Bcl-2, Bcl-X_L, Bax, and Bid, have all been shown to form ion-conducting channels in synthetic membranes *in vitro*.

The other subset of Bcl-2 family proteins appears to have in common only the presence of the BH3 domain, including Bad, Bik, Bim, Hrk, Bcl-G_S, p193, and APR (Noxa). These proteins are all pro-apoptotic in their function, and their cell death-inducing activity depends on their ability to dimerize with anti-apoptotic Bcl-2 family members, typically functioning as *trans*-dominant inhibitors of proteins such as Bcl-2 and Bcl-X_L.[40] In this regard, the BH3 domain has been shown to mediate dimerization among Bcl-2 family proteins. This domain consists of an amphipathic α-helix ~16 amino acids in length that inserts into a hydrophobic crevice on the surface of anti-apoptotic proteins such as Bcl-X_L. Thus, mutations in the BH3 domain of proteins such as Bad, Bik, Bim, Bcl-G_S, and Hrk that abolish their ability to bind other Bcl-2 family member also abrogate their capacity to induce apoptosis.

Conclusion

Advances in elucidating the molecular mechanisms of apoptosis and its regulation have laid the foundation for a deeper understanding of the pathophysiology of many diseases. More importantly, this work has revealed strategies for therapeutic intervention in a wide range of ailments, including cancer, autoimmune disorders, immunodeficiency, inflammation, ischemic heart disease, stroke, and neurodegenerative diseases. Small-molecule inhibitors of caspases, for example, are now in early clinical trials, with more to come in the near future. Anticancer therapies based on antisense oligonucleotide-mediated suppression of *BCL-2* expression have advanced to Phase III trials. Biological agents that control apoptosis, such as Trail-ligand (Apo2L), will also soon enter clinical trials for patients with refractory metastatic cancers. This progress in translating knowledge about apoptosis mechanisms into the clinical arena suggests rich opportunities for new and more effective treatments for many of the medical illnesses for which adequate therapies currently do not exist.

Abstract

Micronutrients play animportant part in metabolism and in maintaining tissue function. An adequate intake is therefore necessary, but provision of excess supplements to people who do not need them may be harmful. Single micronutrient deficiency states are comparatively easily recognised and treated. Subclinical deficiency, often of multiple micronutrients, is themost difficult to recognise, and laboratory assessment is often complicated by the acute phase response. Clinical benefit is most likely in those people who are severely depleted and at risk of complications, and is unlikely if this is not the case. There is a little evidence for supplements leading to a reduction in the incidence of infections of the elderly population, in coronary artery disease, or in the malignant disease. The best evidence for benefit is in the critical illness, and in children in developing countries who consume a deficient diet. More clinical trials are required along with good clinical outcomes to optimise the intake of prevention and treatment of disease.

Key Words*: Micronutrients, Supplements, Disease*

Introduction

The growing interest in the importance of the micronutrients (essential trace elements and vitamins) in optimising health, and in prevention or treatment of disease. This stems partly from the increase in knowledge and understanding of the biochemical functions of these nutrients, but also from the extensive but less well founded commercial claims for such substances. It is important that doctors and other health professionals are aware of the evidence for the nutritional essentiality of these sub- stances, and for the situations where an increased intake may lead to clinical benefit.

This review will therefore consider current knowledge of the requirements in health, those people at risk of an inadequate intake, and the conditions where supplements may be clinically required. The review will focus only on the generally accepted essential inorganic micronutrients (trace elements) and organic micronutrients (fat soluble and water soluble vitamins) for which deficiency states, with biochemical, physiological, or structural changes, have been clearly reported—such states occur after pro- longed consumption of a diet lacking the single nutrient under consideration, and are uniquely corrected by addition of the nutrient back into the diet. Other nutrients for which there are no confirmed deficiency states, but where supplements are often taken, such as v-3 fatty acids, glucosamine, coenzyme Q, will not be considered[1].

Functions

Cofactors in metabolism—follow components are every now and again associated with regulating catalyst action or are an indispensable piece of chemical prosthetic gatherings—for instance, zinc is a cofactor for more than 100 compounds, though selenium is required as selenocysteine inside the protein glutathione peroxidase.

N Coenzymes in metabolism—numerous vitamins or metabolites of vitamins are required to have a dynamic influence inside complex biochemical reactions, for instance, riboflavin and niacin in the electron transport chain, or folic corrosive as a major aspect of methyl assemble exchange. These responses are basic to delegate digestion and guarantee usage of the real supplements to give vitality, proteins and nucleic acids.

N Genetic control—zinc "fingers" are transcription control factors that predicament to DNA and direct interpretation of receptors for steroid hormones and different variables.

N Antioxidants—a significant part of the well known enthusiasm for the micronutrients comes from the acknowledgment that a large number of the micronutrients have hostile to oxidant properties. Oxidative digestion unavoidably prompts age of responsive oxygen species (ROS) or "free radicals", which can possibly bring on additional oxidative responses, particularly to those parts of the phone in a moderately decreased state, for example, cell layers or nucleic acids.[1] The potential to cause harm is restricted by instruments that incorporate direct extinguishing of oxidant action by tocopherols (vitamin E) or carotenoids (vitamin An), or protein frameworks to discard the results of oxidation—super-oxide dismutase (either zinc/copper or manganese subordinate) and glutathione peroxidase (selenium subordinate)[2].

Reference Nutrient Intakes of Micronutrients

Numerous nations have created recommendations for admission of micronutrients in the typical eating routine. These have been founded on the watched admissions in the solid populace, combined with little quantities of point by point supplement adjust studies, and research facility assessments of blood and tissue status related with specific levels of admission. Qualities have been set for the admission of every micronutrient beneath which a clinical inadequacy state is progressively likely, or above which a lethality state is probably going to create. Despite the fact that these are applicable for populaces, the trouble is to decide how sufficient is the admission for a specific individual. This is particularly the case for specific micronutrients where it is perceived that there might be extra advantages as far as tissue function if the intake is to some degree more important than that required, just to keep an insufficiency state from creating[2,3].

FinancialImpacts

Numerous gatherings in the populace have a poor admission of supplements because of an intricate association amongst social and monetary conditions. In this way individuals from a poorer foundation may well take less crisp products of the soil . Such gatherings may profit by some type of micronutrient supplement, albeit coordinate examinations are missing of arrangement of supplements instead of enhancing dietary admission[4,5].

Population Groups with Known Poor Intake or Increased Requirements

Certain gatherings inside the populace are known to have a poor or lacking admission. For instance, youths and adolescents may have a deficient admission of drain and different wellsprings of calcium,[6] and elderly individuals in nursing homes and private care have a lacking vitamin D intake[5]. Furthermore, regardless of there being a satisfactory supply of most micronutrients in the sustenance accessible in nursing homes, there is a high occurrence of biochemical inadequacy for most micronutrients, including zinc, press, vitamin C, and riboflavin[5]. There are numerous conceivable reasons for inadequate admission or retention, including anorexia, failure to cut up nourishment, or poor nourishment introduction.

Besides, certain gatherings have expanded prerequisites—eager moms require expanded folate both before origination and in the primary trimester,[2] smokers require extra vitamin C,[3] and individuals who are recuperating from an intense disease or after surgery likely have numerous requirements[7].

It would be altogether fitting for gatherings of this sort to take supplements to guarantee their aggregate admission, including their eating routine, was sufficient.

Other Biochemical Effects—Uncertain Clinical Consequences

As such a significant number of the micronutrients are engaged with parts of the cancer prevention agent barrier systems, it has been expected that imperfect cancer prevention agent movement will prompt oxidative harm to tissues or to parts of the cell, with conceivably genuine outcomes.

Oxidative Harm and Coronary Artery Disease

On account of the solid connection between oxidised low thickness lipoprotein and advancement of coronary vein malady, together with the lower frequency of coronary conduit illness in nations where there is a high admission of cancer prevention agents, it has been normal that an expanded admission of cell reinforcements would lessen the rate and complexities of coronary illness. Some little investigations did at first recommend advantageous impacts from taking vitamin E supplements[8,9].

Notwithstanding, more as of late various extensive scale trials have neglected to show such an advantage, for instance, the HOPE study[10] considered 9541 patients with high danger of coronary illness, who got 400 IU vitamin E in addition to ACE inhibitors and demonstrated no advantage from vitamin E supplements. The GISSI study[11] in Italy neglected to demonstrate any advantage from the utilisation of vitamin E in 324 patients after myocardial dead tissue, in spite of the fact that patients benefitted from an expanded admission of polyunsaturated unsaturated fats.

Additionally, the Medical Research Council/British Heart Foundation study[12] of 20 333 high hazard UK grown-ups demonstrated that an admission of vitamin E (600 mg), vitamin C (250 mg), and b carotene (20 mg), over a five year time frame had no critical advantage on frequency or movement of coronary illness.

An exhaustive survey of concentrates by the American Heart Association reasoned that cardiovascular sickness lessening can be accomplished by long haul utilisation of an all around adjusted eating routine together with standard physical movement, and that there was no extra advantage from utilisation of micronutrients at levels surpassing these acquired from such a diet[13].

Moreover, Miller and coworkers[14]. have distributed a meta-examination of 19 clinical trials inspecting the part of vitamin E, either alone (nine investigations) or together with different cell reinforcements (10 considers) in a sum of 135 000 members. They presumed that high admission of vitamin E at dosages of .400 IU/day or more conveyed no advantage, and without a doubt may expand all reason mortality. They assessed that the expanded hazard may begin at measurements as low as 150 IU/day. Supplements of even lower dosages than this may however convey a peripheral advantage. An especially essential component of this meta examination is the measurements impact of vitamin E. It has for some time been trusted that the higher the measurements of vitamin E the better would be any potential advantage, and that there were no unsafe impacts related with a high dosage. This meta examination makes it clear that high measurements of any supplement are probably going to be related with hurtful symptoms. On the off chance that valuable impacts are gotten by remedy of a sub-clinical lack, at that point the dosage expected to do as such should be painstakingly settled.

Oxidative Harm and Neoplastic Sickness

It has additionally been expected that an expanded admission of cell reinforcements would be valuable in lessening the rate of different types of growth, by diminishing oxidation actuated transformations in DNA. In fact this is the most well-known reason given in the USA for utilisation of such supplements[15]. Apart from the investigations of selenium, including that said above, and an examination on liver growth in China40 different investigations have been disillusioning. Specifically, an investigation over a five to eight year time of 29 133 Finnish male smokers who got b carotene (20 mg), a tocopherol (50 mg), or both, demonstrated a 18% higher frequency of lung disease in the b carotene gathering, though a tocopherol had no effect[16]. An examination from the USA of 18 314 smokers, previous smokers, and asbestos labourers who got 30 mg b carotene and 25 000 IU vitamin A [17]over a four year term, additionally demonstrated that the supplemented aggregate had a higher relative danger of lung malignancy of 1.28.

Different investigations have given clashing confirmation. The attendant wellbeing study in USA of 88 758 ladies demonstrated that folate admission or supplements for under 15 years did not altogether lessen the danger of colon disease, but rather more prominent than 15 years' supplementation reduced risk[18]. The advantage of folate is by all accounts most prominent in those taking in excess of two mixed beverages for each day[19]. However, in a similar gathering of ladies there was a higher frequency of non-Hodgkin's lymphoma in those supplemented[20]. Other investigations have demonstrated that long haul vitamin E (more prominent than 10 years) may decrease bladder malignancy mortality[21].

The worry about supplements and disease was com-beat in a further meta-investigation that demonstrated that with the conceivable special case of selenium, cell reinforcement supplements did not lessen the danger of gastric or intestinal malignancies, but instead, in the event that anything, to some degree expanded that hazard by around 6%.47 This prompted the Lancet featuring in an article—"The prospect that vitamin pills may do no great as well as execute their clients is a frightening hypothesis given the immense amounts that are utilized as a part of certain communities"[22].

In any case, strangely, and on a more positive note, a current investigation of the eating routine of the individuals who participated in the lung tumor think about performed in

Finland[23] demonstrated that when a cell reinforcement record was utilised that joined all cell reinforcements in sustenances eaten by the members, the subjects in the most noteworthy quintiles of cancer prevention agent admissions had a lower rate of lung cancer[24]. So no doubt when taken in nourishments cell reinforcements may have a gainful impact, though high dosage filtered supplements might be unsafe.

There have additionally been some intriguing discoveries from the SU.VI.MAX contemplate on 13 000 grown-ups, matured over 60 years, from the overall public in France[25]. A supplement of similarly low measurements of individual cancer prevention agents (vitamin C 120 mg, vitamin E 30 mg, b carotene 6 mg, selenium 100 mg, zinc 20 mg) was examined over a middle follow up time of 7.5 years. Albeit no vital contrasts were found in all out malignancy occurrence, ischaemic coronary illness, or all reason mortality, a noteworthy distinction was seen amongst male and female reactions. The sex stratified investigation indicated bring down tumor frequency and all reason mortality in men who took the supplement yet not in ladies. A further examination of the information recommended this may be a consequence of the poorer benchmark status of b carotene in men, which was dynamically rectified amid the time of supplementation. A further intriguing outcome from this examination was that the men getting supplements had a lower occurrence of prostate tumor if PSA toward the start of the examination was typical, however an expanded frequency if PSA at benchmark was raised[26]. The essentialness of these outcomes in connection to advancement of prostate growth requires advance examination.

In rundown, the circumstance in regards to cell reinforcement supplements and tumor is as of now confounded. There would appear to be little uncertainty that an eating routine rich in cell reinforcements is probably going to limit the danger of specific kinds of disease, however the circumstances where particular supplements might be valuable requires considerably additionally work to focus on the populaces and the admissions of micronutrients that might be helpful, and to restrict the likelihood that these might be destructive.

Oxidative Harm and Eye Infection

The Age Related Eye Disease Study (AREDS) Group[27,28] detailed the outcomes from a huge forthcoming twofold visually impaired fake treatment controlled investigation crosswise over 11 focuses in the USA. The supplements were of vitamin C (500 mg) in addition to

vitamin E (400 IU) in addition to b carotene (15 mg), or zinc (80 mg) in addition to copper (2 mg), or both of these. 4629 patients were followed up for a mean time of 6.3 years. The essential conclusions from this examination were right off the bat that there was no critical distinction being developed or movement of age related waterfall. Be that as it may, there was a critical diminishment in the movement of age related macular degeneration, the combi-country of cell reinforcements together with zinc being best and prompting a lessening of around 25%.

Non-Specific Functional Effects

Immune Function

As a significant number of the micronutrients are engaged with parts of the cancer prevention agent barrier systems, it has been expected that imperfect cancer prevention agent movement will prompt oxidative harm to tissues or to parts of the cell, with conceivably genuine outcomes.

Infections in Youngsters

Zinc deficiency is common in kids in creating nations where loose bowels is additionally a vital issue. In six of nine trials, zinc supplementation essentially lessened the rate of loose bowels, and in five of these there was a lower occurrence of pneumonia[29]. In addition, in intense the runs trials, zinc supplemented kids had a 15% lower prob-capacity of proceeding with the runs on a given day, and in persevering the runs trials, there was a 24% lower likelihood of proceeding with the runs.

Vitamin A supplements in populaces with poor vitamin A status, have been appeared to lessen mortality from loose bowels in group studies, and passings from pneumonia in measles studies[30].

A conceivable cooperation amongst zinc and vitamin A status has been investigated by Rahman and colleagues[31]. In an examination on 800 youngsters (matured 12– 35 months) in Bangladesh, a two week supplement of zinc, vitamin A, both, or fake treatment was given to kids who were then followed up for a half year. Consolidated zinc and vitamin A synergistically decreased the commonness of constant loose bowels and looseness of the bowels. Curiously, zinc alone was related with a noteworthy increment in intense lower respiratory contamination, yet this unfriendly impact was decreased by collaboration amongst

zinc and vitamin A. In an investigation of tuberculosis in Indonesia, supplementation with zinc and vitamin A prompted substantially before determination of radiological changes and time to sputum negativity[32].

In an extensive late examination in India on private school-kids with biochemical confirmation of poor status for a few micronutrients, a multi-micronutrient supplement did not lessen the occurrence of normal youth contaminations, but rather reduced the term of such illnesses[33].

HIV Disease and AIDS

Weight reduction is a typical issue in HIV, and patients are every now and again found to have anomalies of plasma mineral and follow component focuses, particularly of zinc, selenium, and magnesium[34]. There are various connecting factors, including loss of hunger, diminished assimilation, diarrhoea and urinary misfortunes, and the impacts of redistribution from plasma to tissues because of the reaction to infection[35].

Of uncommon importance is the part of follow components and different micronutrients in cell reinforcement guard. Zinc and copper are basic for cytoplasmic superoxide dismutase, manganese for the mitochondrial protein, and selenium is a piece of the prosthetic gathering of glutathione peroxidase. Loss of cancer prevention agent action will prompt expanded actuation of atomic factor-kB (NF-kB), which is a key controller of HIV replication[36]. There is prove that decrease in plasma selenium parallels the loss of CD4+ cells, and that low levels of selenium in youngsters is identified with speedier sickness movement and to mortality. In spite of the fact that supplementation may prompt biochemical change, demonstrating that this prompts enhanced clinical result remains controversial[37]. In any case, one examination suggests that supplementation will postpone movement of the seriousness of HIV[38].

Selenium Insufficiency and Harmfulness of Disease

In spite of the fact that not straightforwardly identifying with resistant capacity, a different line of examination has potential results on the occurrence of contamination. This is the finding that when an ordinarily kindhearted strain of Coxsackie B3 infection is infused into selenium lacking mice, the infection changes to a more harmful shape that may cause serious cardiomyopathy[39]. The viral genome was found to have transformed in six districts when

the infection was refined toward the finish of the examination. A similar gathering has likewise discovered that flu infection causes more serious lung malady in selenium insufficient mice, presumably additionally because of genome transformation—they distinguished 29 nucleotide changes in the M1 lattice protein, an inward popular protein[40]. The importance of these discoveries to human irresistible illness stays to be built up, yet in the event that there are similar impacts in people, there are suggestions for enhancement of selenium status.

Contaminations in the Elderly Populace

There has additionally been a conviction that elderly individuals when all is said in done, who frequently have poor micronutrient status and weakening resistant capacity, would especially profit by supplements. This field of work has experienced severely the current disclosures with respect to adulteration of work by Dr Ranjit Chandra—his production in the Lancet was one of only a handful couple of concentrates to offer confidence to the speculation that supplements would decrease irresistible malady in an elderly population[41]. This examination has now been discredited[42].

One critical examination included systematised elderly patients in France, where 725 patients more than 65 years of age partook in a two year twofold visually impaired fake treatment controlled trial, where they got either follow components (20 mg zinc/100 mg selenium), vitamins (vitamin C 120 mg, b carotene 6 mg, a tocopherol 15 mg) or both of these[43]. The outcomes were suggestive, however did not achieve measurable noteworthiness, of a diminishment in respiratory diseases over the two year time frame in the gathering getting follow components, with halfway outcomes for the vitamin gatherings. This outcome was however especially striking in one individual nursing home concerning consolidated respiratory and urogenital contaminations, where in the 80 patients considered, the gathering getting follow components alone had a noteworthy decrease in diseases, while the gatherings accepting vitamins, either alone or together with follow components did not[44]. Specifically noteworthy in the fundamental examination was the finding that sero-change to flu immunization was altogether better in the follow component gather alone, and essentially more awful in the gathering accepting vitamins. This observing critically requires to be examined in future examinations, as it would have suggestions on whether the elderly populace would profit more from focused particular supplements instead of a general multivitamin and follow component supplements. We have however been not able

recogniseany change in sero-transformation by one month's supplementation with an adjusted follow component and vitamin preparation[45].

Taken by and large, a meta-examination demonstrated that there is pretty much nothing if any advantage from a multivitamin and mineral supplement, as far as occurrence of diseases in an elderly population,[46] and this has as of late been affirmed in a vast free living populace in Scotland[47].

Bone Capacity

Postmenopausal ladies specifically are in danger of osteoporosis, and in spite of the fact that the ailment isn't caused by absence of calcium and vitamin D, sufficient arrangement of these smaller scale supplements is advantageous in keeping up and surely expanding bone mass[48]. There is a positive connection between's zinc admission and bone mineral thickness in moderately aged pre-menopausal women[49]. A controlled trial of copper supple-mentation in moderately aged ladies demonstrated no misfortune in bone mineral thickness (BMD) in the copper supplemented amass contrasted and a noteworthy decline in BMD in the control

Group[50]. A little trial of calcium, zinc, manganese, and copper supplements demonstrated a beneficial outcome on spinal BMD in post-menopausal women[51]. Furthermore, there is developing confirmation of the significance of ideal vitamin K allow in carboxylation of bone proteins and complexation of calcium, to expand bone mass[52]. Particular proof to advance dietary admission is as yet missing, and pending the consequences of future trials, the present best counsel is to guarantee an eating regimen high in products of the soil to guarantee sufficient admissions of all vitamins and follow elements[53].

Conclusion

Micronutrients play a central part in metabolism and in the maintenance of tissue function. An adequate intake is therefore necessary but provision of excess supplements to people who do not need them may be harmful. Clinical benefit is most probable in those people who are severely depleted and at risk of complications, and is unlikely if this is not the case. Much more research are needed to characterise better markers of micronutrient status both in terms of metabolic effects and antioxidant effects, so that at risk patients can be identified and supplementation modified accordingly. Large scale trials of different doses of micronutrients

are required with precise outcome markers to optimise the intakes in different groups of patients as well as in the general population.

Abstract

The greatest threats to developing teeth especially in field of dentistry are dental caries and traumatic injury. A primary goal of all restorative treatment is to maintain pulp vitality so that normal root development.If pulpal exposure occurs, then a pulpotomy procedure aims to preserve pulp vitality to allow. Pulpotomy technique basically consists of removing the coronal pulp and fixing the radicular pulp with a medicament. It is the most widely accepted clinical procedure for treating primary teeth with coronal pulp inflammation caused by caries with no involvement of the radicular pulp. Vital pulpotomy is considered as a one-stage procedure with the objective of preserving the vitality, function of the remaining radicular portion of pulp and maintain it asymptomatic without adverse clinical signs or symptoms such as sensitivity, pain, or swelling,So the ideal requisites of any pulpotomy material should be bactericidal, harmless to pulp and surrounding structures, promote healing of remaining radicular pulp without interfering with the physiologic root resorption and not possess any toxicity.calcium hydroxide has been the material of choice for pulpotomy procedures. Recently, an alternative material called mineral trioxide aggregate (MTA) has demonstrated the ability to induce hard-tissue formation in pulpal tissue. The need for more and more new materials is never ending especially in the field of dentistry. Various materials have been formulated, tested and standardized to obtain maximum benefit for good clinical performance. latest bioactive calcium-silicate based material (biodentine),Mineral trioxide aggregate.Hence to analysis the difference between bioactive calcium-silicate based material (biodentine),Mineral trioxide aggregate this review is done.

Key Words: Pulpotomy,Mineral trioxide aggregate,Biodentin,Restoration,primary molars.

Introduction

The preservation of pulpally involved deciduous tooth in a healthy state until the time of normal exfoliation remains to be a great challenges for Pedodontists.Pulpotomy technique consists of removing the coronal pulp and fixing the radicular pulp with medicament. It is commonly usedclinical procedure to preserve the primary teeth with coronal pulp inflammation caused by caries with no involvement of the radicular pulp [1].Restorative materials compatible with physiologic root resorption that determine this choice.A pulpotomy is based on the concept that the inflammation and reduced vascularization, caused by bacterial invasion, are confined to the coronal pulp, while the root pulp remains vital an ideal pulpotomy material should be bactericidal, promote root pulp healing, provide a relatively stable environment for the dentin-pulp complex, stimulate dentin-complex regeneration and not disturb the physiologic process of root resorption [2]. A scientific noise has been generated about several materials some of which have been popular pulpotomy medicaments. Concerns have been raised about the toxicity and potential carcinogenicity of these materials, and alternatives have been proposed to maintain the partial pulp vitality[3].

Over the years, various types of dental materials have been developed to serve different purposes and to be applied to multiple scenarios in the field of dentistry. Mineral trioxide aggregate (MTA), was initially introduced as material for root perforation repair [4].It is primarily composed of tricalcium silicate, tricalciumaluminate, tricalcium oxide, and bismuth oxide [5]. It is formulated of fine hydrophilic particles that solidify in the presence of moisture or blood [6]. MTA was approved by the U.S. Food and Drug Administration for endodontic use in 1998 .Mineral trioxide aggregate (MTA) is a biocompatible material which provides a biological seal. MTA has been proposed as a potential medicament for various pulpal procedures like pulp capping with reversible pulpitis, apexification, repair of root perforations, etc [7] overcoming the disadvantages of MTA Biodentin has several advantages. Hence the present study was done to evaluate the efficacy of MTA and Biodentin as a pulpotomy medicament.

Mineral Trioxide Aggregate

Mineral trioxide aggregate (MTA), is commonly used material for root perforation repair. Over the years its use has expanded to include versatile applications in the field of pediatric dentistry [8]. MTA is a unique material with various advantages. It has been used successfully by pediatric dentists in a variety of clinical applications. However, its drawbacks especially its high cost, discoloration potential, difficulty in handling, and long setting time cannot be overlooked. Despite MTA,noveltricalcium silicate based materials that overcome MTA's key limitations, they are competing to be the next potential dentin substitutes for the various clinical application in which MTA has been used [9]. MTA is a trimineral aggregate, which is composed of tricalcium silicate, tricalicum aluminate, tricalcium oxide, silicate oxide and bismuth oxide material contains calcium oxide (50-75% by weight) and silicon dioxide (15–25%), then they are mixed, they result in the production of tricalcium silicate, dicalcium silicate, tricalcium aluminate and tetracalciumaluminoferrite [10].

The flexural strength is the material's capability to withstand deformation. It is highly recommended to place a wet cotton pellet on top of the placed MTA for the first 24 hours to increase the flexural strength then remove it to avoid the subsequent decrease in the flexural strength 72 hours after MTA receives moisture [11].

The push-out strength is the material's ability to withstand dislodgement. It is a crucial factor for MTA since soon after repair, the material can be dislodged by the tooth function. It was found that the push-out strength of MTA is lower than that of the intermediate restorative material (IRM) or Super ethoxybenzoic acid (EBA)[12].

Both the maximum compressive and push-out strength of MTA was found to be reached several days after mixing [13]. Its properties like sealing ability and marginal adaptation of MTA, was found to be better than the various other restorative materials used for root-end filling (attributed to the MTA expansion in its setting reaction [14]. The retentive strength of MTA, however, was found to be significantly inferior to GIC or zinc phosphate cement as a luting cement [15]. The AAPD recommended the use of MTA for pulpotomies of primary teeth with normal pulps or reversible pulpitis when caries removal results in pulp exposure or after a traumatic pulp

exposure.Clinical trials have revealed that MTA's performance is equal or superior to formocresol (FC), ferric sulfate, and might be considered as one of the favored pulpotomy materials.The introduction of MTA for pulpotomy overcame the drawbacks of FC such as its potential toxicity, caustic nature, and tissue irritation and inflammation upon contact with soft tissue.Farsi et al found that pulpotomized primary molars treated with MTA had significantly more success than those treated with FC [16].Sushynski et al conducted a randomized controlled trial and concluded that MTA demonstrated significantly better radiographic outcomes as a pulpotomy medicament compared to diluted FC which also exhibited a higher frequency of internal root resorption in the FC-treated molars. A recent systematic review and meta-analysis comparing MTA and FC used for primary molar pulpotomy, found that MTA was more effective and showed higher success rate than FC at six to 24-months follow-ups.However, Marghalani et al systematic review and meta-analysis comparing long-term (24 months) clinical and radiographic success of MTA and FC as a pulp-dressing material in pulpotomy treatment in primary molars showed comparable success rate [17].

Types of MTA

There are two basic forms of MTA based on color, gray (GMTA) and white (WMTA). MTA was initially presented as gray Pro-root MTA, however, the potential for discoloration of GMTA lead to the development of WMTA in 2002.

They principally differ in that WMTA was found to have lower quantities of iron, aluminum, and magnesium oxides than GMTA.The reduced ferrous oxide (FeO) was suggested by Asgary and colleagues to be the likely cause of the lighter color of WMTA. Other differences between WMTA and GMTA were reported in the literature. GMTA's crystal size was found to be about 8 times larger than WMTA's crystal size.GMTA also has significantly longer setting time; less radiopacity; solubility; and pH value than WMTA.Concerning the compressive strength, there are conflicting results with one study reporting significantly less compressive strength,while two other studies reported more compressive strength of WMTA compared to GMTA.Furthermore, regarding their antimicrobial behavior, it was reported that GMTA achieved similar antimicrobial action against particular microorganisms at lower concentrations than

WMTA.However, Asgary and Kamran,reported similar antibacterial properties for both types of MTA [18].

Other variations include incorporating resin in the MTA mix to be used as a root canal sealing cement. The purpose was to improve material flow, dentine bonding, and setting time and so to reduce micro-leakage. An example is the MTA Fillapex.However, it was found that adding resin to the materials results in the reduction of the desired free $Ca(OH)_2$ (essential for continued root formation in immature permanent teeth).

The NeoMTA (NuSmile, Huston, USA), on the other hand, is a pure MTA and does not contain resin. It is marketed as a cost effective MTA intended to be used for pediatric pulp therapy. The powder is provided in a lined vial that is re-sealable which facilitates the use of only the needed amount of MTA in each treatment thereby enhancing costeffectiveness. The liquid used for mixing is a gel which makes it easier to mix and apply. In addition, it has a non-staining formulation and a fast setting time. All these features are desirable while delivering treatment to the pediatric patient [19]. Another comparable material is the Neo MTA Plus ,it also possesses a powder-gel formula and is promoted to be used in pulpotomies because it does not stain the tooth structure by replacing bismuth oxide with tantalum oxide for opacity.

Biodentin

Calcium silicate based materials have gained popularity in recent years due to their resemblance to mineral trioxide aggregate (MTA) and their applicability in cases where MTA is indicated. Although various calcium silicate based products have been launched to the market recently, one of these has especially been the focus of attention and the topic of a variety of investigations. is material is the “Biodentine” calcium silicate based product which became commercially available in 2009 and that was specically designed as a “dentine replacement” material [20]. Biodentine has a wide range of applications including endodontic repair (root perforations, apexication, resorptivelesions, and retrograde lling material in endodontic surgery) and pulp capping and can be used as a dentine replacement material in restorative dentistry [21]. The

material is actually formulated using the MTA-based cement technology and the improvement of some properties of these typesofcements, such as physical qualities and handling

Composition of Biodentine states that the powder component of the material consists of tricalcium silicate, dicalcium silicate, calcium carbonate and oxide, iron oxide shade, and zirconium oxide [22]. Tricalcium silicate and dicalcium silicate are indicated as main and second core materials, respectively, whereas zirconium oxide serves as a radioopacity, on the other hand, contains calcium chloride as an accelerator and a hydrosoluble polymer that serves as a water reducing agent. It has also been stated that fast setting time, one unique characteristics of the product, is achieved by increasing particle size, adding calcium chloride to the liquid component, and decreasing the liquid content. The setting period of the material is as short as 9–12 minutes [23].It has shorter setting time is an improvement compared to other calcium silicate materials. Some authors have indicated that there are few studies on the properties of newly developed materials such as Biodentine.The material is characterized by the release of calcium when in solutionTricalcium silicate based materials are also de ned as a source of hydroxyapatite when they are in contact with synthetic tissue [24].

When materials' influences are to be evaluated in terms of pulpal response during vital procedures, in vivo study designs are helpful and animal and human teeth are generally preferred to demonstrate the effects of pulp capping agents [25].These should further be supported by clinical trials to establish a clear picture regarding the general characteristics of the materials. MTA, which is generally considered a gold standard, has been investigated in various human and animal experimental models. On the other hand, studies comparing MTA with Biodentine in terms of vital pulp treatment behavior are rather limited.study to demonstrate the induction of e effective dentinal repair was the one by Tran et al [26] where the material was applied directly on mechanically exposed rat pulps. In their study where Biodentine was compared to MTA and calcium hydroxide in terms of reparative dentine bridge formation, they noted that the structure induced by Ca(OH)2 contained several cell inclusions, also called tunnel defects as previously reported by Cox et al. in 1996.These defective regions were regarded as undesirable areas facilitating the migration of the microorganisms towards the pulp and predisposing the tooth to an endodontic infection. On the contrary, the dentine bridge formation induced by Biodentine

showed a pattern well-localized at the injury site unlike that caused by calcium hydroxide that exhibited an expanding structure in the pulp chamber. e quality of the formed dentine was also much more favorable compared to calcium hydroxide and an orthodentin organization was noted in which dentine tubules could be clearly visualized [27]. Moreover, cells secreting the structure well exhibited DSP expression as well as osteopontin expression, which are critical regulators of reparative dentine formation.

Pulpotomy is another vital pulp treatment method in which Biodentine is advocated to be used. is method is widely used in pediatric dentistry and involves the amputation of pulp chamber and the placement of a material for the preservation of the radicular pulp tissue's vitality. is methodology is specifically useful and preferred when the coronal pulp tissue is mainly involved and a direct pulp capping is not a suitable option [28].

Comparison between MTA and Biodentin

The placement of a root-end filling material during periapical surgery is a procedure of paramount importance to seal the root canal.Several materials have been tested as root-end filling materials, but none of them has been demonstrated to be free from limitation [29].Mineral trioxide aggregate (MTA), a calcium silicate-based endodontic material possesses excellent biocompatibility and sealing ability; thus, it is considered a promising material for various endodontic applications such as pulp capping, pulpotomy,apical barrier formation in teeth with open apexes, repair of root perforations, and as a root canal filling material, besides a root-end filling material.Despite its good physical and biologic properties, some clinicians still claim to have difficulties in handling this material after its preparation to fill a retroprepared root cavity.Several new calcium silicate-based materials have recently been developed, aiming to improve some MTA drawbacks such as its difficult handling property and long-setting time (ProRoot MTA) [30]. Biodentineis among these materials and is claimed to be used as a dentine restorative material in addition to endodontic indications similar to those of MTA.

Compressive Srength of MTA and Biodentin

Biodentine has more prominent biomineralization ability than MTA, with wider calcium and silicon rich layer at material-dentine interface. The setting time is one of the most clinically relevant factors. A long-setting duration may cause clinical problems because of the cement's inability to maintain shape and support stresses during this period.The setting time of MTA-Angelus mixed with water was 8.5 min [31]. In contrast, Biodentine exhibited shorter setting time (6.5 min) though not statistically significant. Accelerated setting reduces the risk of dislodgement and contamination of MTA-like cements when used as root-end filling material.An important feature of a root-end filling material is its handling property [32]. MTA-Angelus is grainy and has a poor consistency, making it difficult to manipulate in clinical situations. In contrast, Biodentine was relatively easier to handle and on thorough amalgamation it rolled into a dough-like consistency that could be easily condensed. Compressive strength is an indicator of the setting process and strength of the material.According to the results of this study, the compressive strength of MTA-Angelus was 41 MPa at 24 h that increased to 76.8 MPa at 28 days. These results are similar to those reported by Torabinejad et al. (40 MPa at 24 h and 67.3 MPa after 21 days). Several studies have reported modifications of MTA to overcome its shortcomings and improve its physical properties.Biodentine exhibited compressive strength of 170 MPa at 24 h that increased substantially to 304 MPa after the material was placed in moisture for 28 days. This value of compressive strength is close to that reported for human dentine (297 ± 24 MPa).The compressive strength of Biodentine was significantly higher than that of MTA at all time intervals. These factors reduce the chances of bacterial contamination. Biodentine like MTA has an ability to initiate and continue the mineralization process. Biodentine has a limitation that it cannot be used in presence of moisture unlike MTA [33].

Biocompatibility of MTA and Biodentin

Biocompatibility of a dental material is a major factor that should be taken into consideration specifically when it is used in pulp capping, perforation repair or as a retrograde filling. During the aforementioned procedures, the material is in direct contact with the connective tissue and has the potential to affect the viability of periradicular and pulpal cells. Cell death under these

circumstances occurs due to apoptosis or necrosis [34]. Therefore, it is essential that toxic materials are avoided and materials promoting repair or that are biologically neutral are preferred during procedures in which the material is directly in contact with the surrounding tissue [35]. Though the information accumulated so far regarding the biocompatibility of Biodentine is rather limited, the available data generally is in favor of the material in terms of its lack of cytotoxicity and tissue acceptability. Han and Okijicompared Biodentine and white ProRoot MTA in terms of Ca and Si uptake by adjacent root canal dentine and observed that both materials formed tag-like structures. They observed that dentine element uptake was more prominent for Biodentine than MTA.

Comparative Strength of MTA and Biodentin

The high mechanical strength of Biodentine may be attributed to the elimination of aluminates that leads to weakening and fragility of the set material as reported by manufacturer. With physical properties superior to those of MTA, especially in terms of setting time and compressive strength, it exhibits the same characteristics of sealing ability, with controlled (size and spatial organization) formation of calcium salts.

Bond Strength

Considering that Biodentine is recommended for use as a dentine substitute under permanent restorations, studies were performed that assess the bond strength of the material with di erent bonding systems. Odaba ş et al. evaluated the shear bond strength of an etch-and-rinse adhesive, a 2-step self-etch adhesive and a 1-step self-etch adhesive system to Biodentine at di erent intervals. No signicant di erences were found between all of the adhesive groups at the same time intervals (12 minutes and 24 hours). When different time intervals were compared, the lowest bonding value was obtained for the etch-and- rinse adhesive at a 12-minute period, whereas the highest was obtained for the 2-step self-etch adhesive at the 24-hour period [36].

Another area of use of Biodentine, specicallyfrom an endodontic point of view, is the repair of perforations, which is likely to be encountered in clinical practice. It is essential that a

perforation repair material should have sufficient amount of push-out bond strength with dentinal walls for the prevention of dislodgement from the repair site [36].

Radiographic Feature of MTA and Biodentin

Radiopacity is an important property expected from a retrograde or repair material as these materials are generally applied in low thicknesses and they need to be easily discerned from surrounding tissues.On radiographic observance, it was noted that initial periapical healing was better in tooth filled with biodentine. However, long-term periapical healing of MTA filled tooth was better. This may due to the fact that MTA has superior marginal adaptation.Superior marginal adaptation of MTA over biodentine may influence sealing ability and clinical success.It is important to note that quality of healing was assessed purely on radiographic changes on monthly basis [37].

Discussion

The main disadvantages of MTA include its high cost, which has been one of its major limitation, its discoloration potential, difficulties in handling the material, prolonged setting time, presence of toxic elements in its composition, difficulty to remove after setting, and it does not have a solvent .Unfortunately, the use of MTA as a dressing for pulpotomies in molars for filling pulp chambers of immature teeth and as an apical barrier has resulted in the discoloration of the crown. The reason of discoloration is debatable, but it has been linked mainly to the interaction between bismuth oxide and the collagen of the tooth tissue and sodium hypochlorite, which is usually used in root canal therapy

In concern of the toxic elements in MTA, mainly in its arsenic content several investigations were conducted and found that the amount of arsenic released is very low.In addition, other factors further minimize the arsenic release from the material into the tissue, such a s the small amounts of the MTA that are actually used clinically, its insoluble nature and the FeO present in its composition with its subsequent stabilizing effect on the arsenic content [38].

In an effort to overcome these disadvantages other tricalcium silicate based materials have been introduced to the market. Bioaggregate (Verio Dental, Vancouver, Canada) and Biodentine (Septodont, Saint-Maur-des-Foss es, France) are tricalcium silicate based materials that have been developed to overcome the drawbacks of MTA while maintaining its desired characteristics and clinical applications.Compared to MTA, Biodentine is a cost effective material that is easier to handle, has a faster setting time (set at about 10-12 minutes), is less soluble, and results in a better seal. It also has alternative radiopacifiers to overcome the discoloration related to bismuth oxide present in MTA [39].

In a study to assess the color stability of MTA Plus compared to Neo MTA plus and Biodentine when used in pulpotomies in immature permanent teeth in the presence of sodium hypochlorite solution, it was found that MTA Plus showed discoloration while Neo MTA Plus and Biodentine did not show discoloration [40].

Conclusion

Vital pulpotomy is considered as a one-stage procedure with the objective of preserving the vitality, function of the remaining radicular portion of pulp and maintain it asymptomatic without adverse clinical signs or symptoms such as sensitivity, pain, or swelling. So the ideal requisites of any pulpotomy material should be bactericidal, harmless to pulp and surrounding structures, promote healing of remaining radicular pulp without interfering with the physiologic root resorption and not possess any toxicity.It may be concluded the sealing quality of Biodentine and commercially available MTA cement (MTA-Angelus) is comparable. The enhancement in handling properties of Biodentine may make it more convenient for use in various clinical applications.

MTA is a unique material with various advantages. It has been used successfully by pediatric dentists in a variety of clinical applications. Despite the many advantages of MTA, its drawbacks especially its high cost, discoloration potential, difficulty in handling, and long setting time cannot be overlooked. With the emergence of other novel tricalcium silicate based materials in

the market, such as Biodentine, that overcome MTA's key limitations, they are competing to be the next potential dentin substitute for the various clinical application in which MTA has been used. However, with the recent introduction of new improved MTA products, MTA-based materials are likely to remain at the heart of good pediatric dental practice for many years to come.

Abstract

Muscular dystrophy (MD) is a group of muscle diseases that weaken the musculoskeletal system and hamper locomotion. Dystrophies are characterized by progressive skeletal muscle weakness, defects in muscle proteins, and the death of muscle cells and tissue. In the 1860s, descriptions of boys who grew progressively weaker, lost the ability to walk, and died at an early age became more prominent in medical journals. In the following decade, French neurologist Guillaume Duchenne gave a comprehensive account of thirteen boys with the most common and severe form of the disease, which now carries his name—Duchenne muscular dystrophy (DMD). It soon became evident that the disease had more than one form. The other major forms are Becker, limb-girdle, congenital, facioscapulohumeral, myotonic, oculopharyngeal, distal, and Emery-Dreifuss muscular dystrophy. The main cause of the Duchenne and Becker types of muscular dystrophy is the muscle tissue's cytoskeletal impairment to properly create the functional protein dystrophin and dystrophin-associated protein complex.

Key words: *Muscular dystrophy, musculoskeletal system, Duchenne muscular dystrophy, cytoskeletal impairment, muscle cell death.*

Introduction

Muscular dystrophy (MD) is a group of muscle diseases that weaken the musculoskeletal system and hamper locomotion.[1,2] Dystrophies are characterized by progressive skeletal muscle weakness, defects in muscle proteins, and the death of muscle cells and tissue.[3]In the 1860s, descriptions of boys who grew progressively weaker, lost the ability to walk, and died at an early age became more prominent in medical journals. In the following decade, French neurologist Guillaume Duchenne gave a comprehensive account of thirteen boys with the most common and severe form of the disease, which now carries his name—Duchenne muscular dystrophy (DMD).It soon became evident that the disease had more than one form. The other major forms are Becker, limb-girdle, congenital, facioscapulohumeral, myotonic, oculopharyngeal, distal, and Emery-Dreifuss muscular dystrophy.[4] Duchenne and Becker muscular dystrophies, being caused by a mutation of a gene located on the X chromosome, predominantly affect males, although females can sometimes have severe symptoms as well. Most types of MD are multi-system disorders with manifestations in body systems including the heart, gastrointestinal system, nervous system, endocrine glands, eyes and brain.[4]Apart from the nine major types of muscular dystrophy listed above, several MD-like conditions have also been identified. Normal intellectual, muscular, behavioral, bowel and sexual function is noticed in individuals with other forms of MD and MD-like conditions.[5,6] Children with muscular dystrophy require complex and long-term health services in multiple settings by a variety of professionals. To protect and promote the well being of this population, it is important to assess and monitor their receipt of care. MD-affected individuals with susceptible intellectual impairment are diagnosed through molecular characteristics but not through problems associated with disability.[7] However, a third of patients who are severely affected with DMD may have cognitive impairment, behavioral, vision and speech problems.[8,9]. This review explains in detain about the individual muscle dystrophy and the gene involved in it.

Signs and Symptoms

Progressive muscular wasting

Poor balance

Drooping eyelids

Atrophy

Scoliosis (curvature of the spine and the back)
Inability to walk
Frequent falls
Waddling gait
Calf deformation
Limited range of movement
Respiratory difficulty
Joint contractures
Cardiomyopathy
Arrhythmias
Muscle spasms
Gowers' sign [10]

Etiology

These conditions are generally inherited, and the different muscular dystrophies follow various inheritance patterns. However, mutations of the dystrophin gene and nutritional defects (with no genetics history) at the prenatal stage are also possible in about 33% of people affected by DMD.[11] The main cause of the Duchenne and Becker types of muscular dystrophy is the muscle tissue's cytoskeletal impairment to properly create the functional protein dystrophin and dystrophin-associated protein complex.

Dystrophin protein is found in muscle fibre membrane; its helical nature allows it to act like a spring or shock absorber. Dystrophin links actin (cytoskeleton) and dystroglycans of the muscle cell plasma membrane, known as the sarcolemma (extracellular). In addition to mechanical stabilization, dystrophin also regulates calcium levels.[11]

Diagnosis

Histopathology of gastrocnemius muscle from patient who died of pseudohypertrophic muscular dystrophy, Duchenne type. Cross section of muscle shows extensive replacement of muscle fibers by adipose cells.The diagnosis of muscular dystrophy is based on the results of muscle biopsy, increased creatine phosphokinase (CpK3), electromyography, electrocardiography and

DNA analysis.A physical examination and the patient's medical history will help the doctor determine the type of muscular dystrophy. Different types of muscular dystrophy affect specific muscle groups.

Often, there is a loss of muscle mass (wasting), which may be hard to see because some types of muscular dystrophy cause a buildup of fat and connective tissue that makes the muscle appear larger. This is called pseudo hypertrophy.

Management

There is no known cure for muscular dystrophy, although significant headway is being made with antisense oligonucleotides.[12] Physical therapy, occupational therapy, orthotic intervention (e.g., ankle-foot orthosis), speech therapy and orthopedic instruments (e.g., wheelchairs, standing frames and powered mobile arm supports) may be helpful. Inactivity (such as bed rest, sitting for long periods) and bodybuilding efforts to increase myofibrillar hypertrophy can worsen the disease.There is no specific treatment for any of the forms of muscular dystrophy. Physiotherapy, aerobic exercise, low intensity anabolic steroids, prednisone supplements may help to prevent contractures and maintain muscle tone. Orthoses (orthopedic appliances used for support) and corrective orthopedic surgery may be needed to improve the quality of life in some cases. The cardiac problems that occur with Emery-Dreifuss muscular dystrophy and myotonic muscular dystrophy may require a pacemaker. The myotonia (delayed relaxation of a muscle after a strong contraction) occurring in myotonic muscular dystrophy may be treated with medications such as quinine, phenytoin, or mexiletine, but no actual long-term treatment has been found.Occupational therapy assists the individual with MD to engage in activities of daily living (such as self-feeding and self-care activities) and leisure activities at the most independent level possible. This may be achieved with use of adaptive equipment or the use of energy conservation techniques. Occupational therapy may implement changes to a person's environment, both at home or work, to increase the individual's function and accessibility. Occupational therapists also address psychosocial changes and cognitive decline, which may accompany MD, as well as provide support and education about the disease to the family and individual. [13]High dietary intake of lean meat, seafood, pulses, olive oil, antioxidants such as leafy vegetables and bell peppers, and fruits like blueberry and cherry is advised. Decreased intake of refined food, trans

fats, and caffeinated and alcoholic beverages is also advised, as is a check for any food allergies.[14]

After diagnosis, medical care may include services in neurology, nutrition, gastroenterology, respiratory care, cardiac care, orthopedics, psychosocial, rehabilitation, and oral care.

Prognosis

The prognosis for people with muscular dystrophy varies according to the type and progression of the disorder. Some cases may be mild and progress very slowly over a normal lifespan, while others produce severe muscle weakness, functional disability, and loss of the ability to walk. Some children with muscular dystrophy die in infancy while others live into adulthood with only moderate disability. The muscles affected vary, but can be around the pelvis, shoulder, face or elsewhere. Muscular dystrophy can affect adults, but the more severe forms tend to occur in early childhood.

Types

Gene Description

Becker Muscular Dystrophy 300376 BMD

Becker muscular dystrophy (BMD) is a less severe variant of Duchenne muscular dystrophy and is caused by the production of a truncated, but partially functional form of dystrophin.[4] Survival is usually into old age.[15] Affects only boys (with extremely rare exceptions)

Congenital Muscular Dystrophy

Multiple at the age of onset: symptoms include general muscle weakness and possible joint deformities; disease progresses slowly; shortened life span.[16]

Congenital muscular dystrophy includes several disorders with a range of symptoms. Muscle degeneration may be mild or severe. Problems may be restricted to skeletal muscle, or muscle degeneration may be paired with effects on the brain and other organ systems. A number of the forms of the congenital muscular dystrophies are caused by defects in proteins that are thought to have some relationship to the dystrophin-glycoprotein complex and to the connections between

muscle cells and their surrounding cellular structure. Some forms of congenital muscular dystrophy show severe brain malformations, such as lissencephaly and hydrocephalus.[4]

Duchenne Muscular Dystrophy 310200 DMD

Duchenne muscular dystrophy (DMD) is the most common childhood form of muscular dystrophy; it generally affects only boys (with extremely rare exceptions), becoming clinically evident when a child begins walking. By age 10, the child may need braces for walking and by age 12, most patients are unable to walk.[17] Life span ranges from 15 to 51.[18] In the early 1990s, researchers identified the gene for the protein dystrophin which, when absent, causes DMD. The amount of dystrophin correlates with the severity of the disease (i.e., the less dystrophin present, the more severe the phenotype). Since the gene is on the X chromosome, this disorder affects primarily males, and females who are carriers have milder symptoms. Sporadic mutations in this gene occur frequently, accounting for a third of cases. The remaining two-thirds of cases are inherited in a recessive pattern.

Dystrophin is part of a complex structure involving several other protein components. The "dystrophin-glycoprotein complex" helps anchor the structural skeleton (cytoskeleton) within the muscle cells, through the outer membrane (sarcolemma) of each cell, to the tissue framework (extracellular matrix) that surrounds each cell. Due to defects in this assembly, contraction of the muscle leads to disruption of the outer membrane of the muscle cells and eventual weakening and wasting of the muscle [18]. The lower prevalence in 2006–2010 may reflect delayed diagnosis of DBMD among cases. It also may reflect a change in parental reproductive choice; however, a separate analysis observed that reproductive patterns of mothers after knowledge of family history of DBMD tended to be similar to those without such family history. The similar estimates for all cases and non-Hispanic white cases reflect the sizable proportion of non-Hispanic white individuals in the future efforts will include expanding surveillance among minority populations. It also may reflect racial/ethnic differences in time to diagnosis and access to care, random fluctuations, or true differences in prevalence of DBMD across these racial/ethnic groups. Conversely, the increased prevalence among Hispanic individuals may reflect suspected underreporting in census estimates for Hispanic children, ages 5 to 9 years. Additionally, our definitions for DMD and BMD, determined from age of onset of signs and

symptoms, may have also biased the true prevalence of each phenotype. Duchene and Becker muscular dystrophy (DBMD) may occur in multiple sons within a family and is associated with variable manifestations among brothers. Common medical complications include loss of ambulation, scoliosis, and cardiomyopathy.

Birnkrant analyzed pulmonary and cardiac function in sibling pairs with Duchenne and Becker muscular dystrophies and found discordant pulmonary outcome among 3 of 7 pairs and discordant cardiac outcome in 3 of 6. They concluded that this variation could have implications for using genotype information to predict the clinical course of DBMD and response to treatments. The observed variability in expression between brothers with the same mutation underscores this point. Although the clinical outcome of older brothers predicted those of their younger brothers for loss of ambulation, we did not find it to be predictive for development of scoliosis or cardiomyopathy in this dataset with the small sample sizes for these milestones. Furthermore, there were sibships for which the differences in reaching clinical milestones were striking, as much as a 6 year, 9 month difference for ceased ambulation, a 3 year 10 month difference for scoliosis ≥ 20°, and an 11 year 11 month difference for cardiomyopathy. This natural variation in clinical outcome among boys with identical dystrophin gene mutations and similar modifying gene profiles suggests that trials of therapeutic interventions will likely require a large number of subjects to detect a significant effect size.

Distal Muscular Dystrophy 254130 DYSF

Distal muscular dystrophies' age at onset: 20 to 60 years; symptoms include weakness and wasting of muscles of the hands, forearms, and lower legs; progress is slow and not life-threatening.[15]

Miyoshi myopathy, one of the distal muscular dystrophies, causes initial weakness in the calf muscles, and is caused by defects in the same gene responsible for one form of LGMD (Limb Girdle Muscular Dystrophy).[4]

Emery-DreifussMuscular Dystrophy 310300, 181350 EMD

Emery-Dreifuss Muscular Dystrophy patients normally present in childhood and the early teenage years with contractures. Clinical signs include muscle weakness and wasting, starting in

the distal limb muscles and progressing to involve the limb-girdle muscles. Most patients also suffer from cardiac conduction defects and arrhythmias that, if left untreated, increase the risk of stroke and sudden death.

There are three subtypes of Emery-Dreifuss Muscular Dystrophy, distinguishable by their pattern of inheritance: X-Linked, autosomal dominant and autosomal recessive. The X-linked form is the most common. Each type varies in prevalence and symptoms. The disease is caused by mutations in the LMNA gene, or more commonly, the EMD gene. Both genes encode for protein components of the nuclear envelope. However, how these mutations cause the pathogenesis is not well understood.[18]

FacioscapulohumeralMuscular Dystrophy 158900 DUX4 FSHD

Facioscapulohumeral muscular dystrophy (FSHD) initially affects the muscles of the face, shoulders, and upper arms with progressive weakness. Symptoms usually develop in the teenage years. Some affected individuals become severely disabled. The pattern of inheritance is autosomal dominant, but there are a significant number of spontaneous mutations. Seminal research published in August 2010 documents that two defects are needed for FSHD, which for the first time provides a unifying theory for the underlying genetics of FSHD. The first is the deletion of D4Z4 repeats and the second is a "toxic gain of function" of the DUX4 gene.[4, 19-20]Facioscapulohumeral muscular dystrophy (FSHD) occurs both in males and females.

Limb-Girdle Muscular Dystrophy

Limb-girdle muscular dystrophy is also called LGMD. Affects both boys and girls. LGMDs all show a similar distribution of muscle weakness, affecting both upper arms and legs. Many forms of LGMD have been identified, showing different patterns of inheritance (autosomal recessive vs. autosomal dominant). In an autosomal recessive pattern of inheritance, an individual receives two copies of the defective gene, one from each parent. The recessive LGMDs are more frequent than the dominant forms, and usually have childhood or teenage onset. The dominant LGMDs usually show adult onset. Some of the recessive forms have been associated with defects in proteins that make up the dystrophin-glycoprotein complex.[4] Though a person normally leads a normal life with some assistance, in some extreme cases, death from LGMD occurs due to cardiopulmonary complications.[21]

MyotonicMuscular Dystrophy 160900, 602668 DMPK, ZNF9

Myotonic muscular dystrophy is an autosomal dominant condition that presents with myotonia (delayed relaxation of muscles) as well as muscle wasting and weakness.[22] Myotonic dystrophy varies in severity and manifestations and affects many body systems in addition to skeletal muscles, including the heart, endocrine organs, eyes, and gastrointestinal tract.

Myotonic muscular dystrophy type 1 (DM1), also known as Steinert disease, is the most common adult form of muscular dystrophy. It results from the expansion of a short (CTG) repeat in the DNA sequence of the DMPK (myotonic dystrophy protein kinase) gene. Myotonic muscular dystrophy type 2 (DM2) is much rarer and is a result of the expansion of the CCTG repeat in the ZNF9 (zinc finger protein 9) gene. While the exact mechanisms of action are not known, these molecular changes may interfere with the production of important muscle proteins.[23]

Oculopharyngeal Muscular Dystrophy 164300 Pabpn1

Oculopharyngeal MD's age at onset: 40 to 70 years; symptoms affect muscles of eyelids, face, and throat followed by pelvic and shoulder muscle weakness, has been attributed to a short repeat expansion in the genome which regulates the translation of some genes into functional proteins.[24]

Lijing Quyang 2012, concluded that among children with special health care needs, those children having muscular dystrophy have lower family socioeconomic status than children without muscular dystrophy and also had more negative health care experiences. The negative healthcare experiences appear to be explained by the association with lower socioeconomic status. Adjusting for multiple factors, muscular dystrophy was not associated with lower likelihood of a medical home. Children with muscular dystrophy incurred substantially more negative financial and employment impacts on family members than did other children in the survey, independent of household socio-demographic characteristics. There is a need to identify effective strategies to help families and caregivers cope with muscular dystrophy [25].

Conclusion

This review provides a brief insight on the etiology, types, genes involved, management and prognosis of muscle dystrophies. Genes explained in detail helps the clinician to arrive at an appropriate diagnosis.
